The Treatment of Congenital Dislocations of the Hip by the Bloodless Method.—M. P. Redard states that this method ought to be tried on patients from two to twelve years of age. In young patients the method, with proper technique, is free from danger and generally gives excellent results.

Some Remarks on Heredity.—A. Macswain declares that no marriage should ever be contracted without a clean health record involving both male and female. He believes that man is not what environment makes him, but is to a large degree what heredity makes him.

Multiple Pregnancy with Report of Cases.—A. W. Shea states that heredity is an important factor in multiple pregnancy. In a few over seven hundred cases, he finds nine instances—eight of twins and one of triplets.

Gastro-Enteritis Complicating Congenital Syphilis.—Robert W. Hastings reviews four cases which he observed in the Boston Floating Hospital last summer, all of which resulted fatally.

Experience in Operations for Typhoid Perforation.—By Hugh M. Taylor. See Medical Record, vol. lvi., p. 910.

A Brief Summary of the Indications for Operations upon the Stomach.—By Max Einhorn. See Medical Record, vol. lvi., p. 637.

Ureterectomy.—By J. Wesley Bovée. See Medical Record, vol. lvi., p. 905.

Canadian Journal of Med. and Surgery, Feb., 1900.

Extreme Emaciation in Hysteria, with Notes of a Case.—T. Beath reports the case of a young girl, who, in heavy clothing, weighed forty-three and three-quarter pounds. She had never menstruated. Her organs were normal, but she complained of deafness without apparent cause. In the fecal evacuations for the first two weeks was tough, slimy mucus. Four weeks of partial segregation and Weir Mitchell treatment saw her well on the way to recovery. Beath, in reviewing this case, calls attention to: (1) The extreme emaciation; (2) the comparative absence of other symptoms; (3) the nosological place of mucous colitis. He emphasizes the fact that there is an hysterical symptom (indefinite abdominal pain associated with the discharge of long strings of mucus per anum and usually constipation) which is in no way associated with colitis.

The Relation of Insanity to Pelvic and Other Lesions.—A. T. Hobbs, after discussing this subject, notes the relative value which the various lesions have in the production or in the maintenance of cerebral disturbance: 1. Utero-ovarian disease of an inflammatory origin received attention in ninety-six cases. The recovery rate following the elimination of these derangements was exactly fifty per cent. 2. Utero-ovarian displacements being corrected in forty-seven cases were followed by thirty-six per cent. of recoveries. 3. Utero-ovarian tumors and vaginal lesions of a non-inflammatory type being attended to in thirty cases were succeeded by twenty-six per cent. of mental recoveries.

The Smallpox Outbreak in Essex.—P. H. Brice sums up four remarkable facts from the statistics of this outbreak: (1) The practically absolute protection of a previous attack; (2) the practically absolute protection of a prior vaccination when a good cicatrix is present; (3) the power of a recent vaccination running concurrently in the system to modify greatly the severity of the disease; (4) a lymph of attenuated virulence does not seem to have done more than modify the severity of the disease.

A New Epoch in Hospital Evolution.—Ernest Hall advocates the development of an institution specially adapted for the treatment of those who have manifested psychic abnormality and have marked physical lesion. While not conflicting with the general hospital nor the asylum, its purpose would be to receive and treat (1) aggravated forms of nervous disease, and (2) cases of insanity in which a definite local lesion could be found.

Address in Surgery.—By W. B. Coley. See Medical Record, vol. lvi., p. 427.

Medicine, February, 1900.

Curability of Epilepsy, and How it May be Accomplished.—William B. Spratling gives the treatment of cases of idiopathic epilepsy at the Craig Colony. The patient is under the entire control of authority. First, he is to be reconstructed physically. For this various means are employed—medicines, systematic occupation, gymnastic exercises, baths, special feeding, and moral agencies. All the while he is being studied for aura and the cause of the disease. He must not overeat, nor use tobacco to excess. Alcoholic stimulants are forbidden. His former manner of life is changed as much as possible. If he cares for any particular work, he is encouraged in its pursuit. Excellent results have followed this treatment.

Gastro-Intestinal Infections in Infants. I. A. Abt states that the opinion is general among bacteriologists and clinicians that: 1. The acute gastro-intestinal disorders of children cannot be attributed to a specific form of bacteria. 2. The toxic symptoms of such infection depend upon the introduction into the alimentary canal of poisonous substances contained in food. 3. Bacteria may be introduced from without; or the ordinary saprophytic bacteria in the canal may assume special virulence. 4. The most severe disturbances are caused by the metabolism of bacteria. 5. Specific intestinal infection may occur in infants. Typhoid fever, though infrequent, may occur.

A Case of Blastomycetic Dermatitis—Clinically and Histologically, an Epithelioma.—W. E. Coates declares that the so-called blastomycetic growths occupy a position closely akin to tumor growths both malignant and benign. He presents the case of a man thirty-seven years of age who exemplifies the statements he makes.

The Topical Application of Iodoform in the Treatment of Tuberculous Affection of Serous Membrane, with Cases.—By Zera J. Lusk. See Medical Record, vol. lvi., p. 684.

Immunization through Vaccination.—By D. P. Austin. See Medical Record, vol. lvi., p. 643.

The Montreal Medical Journal, January, 1900.

West African Medicine.—Charles G. L. Wolf states that in malaria hot spirits and quinine are given, with perhaps antipyrin or phenacetin. The treatment of severe cases of malaria is practically identical with that of Brand. "Craw-craw" is a very interesting disease which has afflicted the white population and is one of the most difficult things in the world to cure. The most frequently used toxic agent on the coast has been till recently the Calabar bean. It is used to poison human beings as well as horses. The two poisons next in use are those of sasswood and the strychnos bean. Two other methods used by the assassin are the mixture of powdered glass in the victim's food and the introduction of mud containing tetanus bacilli together with grit into the victim's shoes.

Report of a Case of Colles' Fracture which Led to a Suit for Malpractice and Prolonged Litigation.—T. M. Conerty gives the history of a case of Colles' fracture treated by him. Some time after the accident a "sore" developed on the patient's arm—a strumous boy—due to the devitalization of tissue from the fall and subsequent infection from gross negligence on the part of the parents. There is now a slight deformity due to cicatricial contraction. The father of the boy, who has sued for damages, was at the time he began the action under an order of commitment to jail for debt. No matter, therefore, how successful the defence may be, the physician must pay the costs of defence.

Electrical Burns.—J. M. Elder gives Dr. Sharpe's description of such injuries, adding any differences he has himself noticed. 1. The burn is at first dried and crisp, the site being bloodless; later, oozing occurs. All the symptoms of moist gangrene will be present. 2. Pain in some patients is slight, in others severe. 3. Some patients experience shock, some do not. 4. As to prognosis, recovery is from one and one-half to five times as long as in the case of other burns. 5. The ascending degeneration following these burns affects chiefly the striped muscle tissue, and is often extensive. Treatment is very unsatisfactory—excision, amputation, and skin-grafting being often necessary.

A Case of Hæmatometra.—William Gardner operated on such a case, the microscopical examination of which excluded all malignant characteristics. The most probable explanation of the occlusion of the cervix which led to the accumulation of the menstrual flow seemed to be adhesive inflammation due to the prolonged pressure of the cup of the prolapsus pessary.

Some Retinal Complications in Chlorosis.—H. McL. Kinghorn reports three cases in which the most important points are: 1. Only one eye was affected. 2. The onset was sudden. 3. Improvement was rapid under iron. 4. The neuro-retinitis and hemorrhages occurred well on in the disease. 5. Hypermetropia was present in both the cases with neuro-retinitis.

A Case of Janiceps.—Andrew Macphail describes this monster which was sent to him from Jamaica, of which place the parents are natives. The specimen shows the spinal columns and backs of the crania to be separate, while the thoraces and faces coalesce anteriorly.

A Rare Form of Pyosalpinx Complicating Uterine Myoma.—William Gardner and Maude E. Abbott report the interesting features of this case to be: (1) The existence of pyosalpinx without any signs of inflammation of the surrounding parts; (2) the combination of pyosalpinx with myoma; (3) excentric hypertrophy of the tube.

The Place of Physical Training in a School System.—R. Tait McKenzie emphasizes the necessity of scientific physical training in schools. The years of most rapid growth are those of school life between eight and seventeen years.

On the Etiology and Symptomatology of Goitre.—By J. George Adami. See Medical Record, vol. lvii., p. 119.

Surgical Gleanings from Abroad.—By L. Coyteux Prevost.

Dublin Journal of Medical Sciences, February, 1900.

The Clinical Features of Beri-Beri.—C. Norman enumerates and discusses the following features of beri-beri: Disturbances of sensation, exaggerated reflexes, later diminished; paresis of the peroneal muscles and foot flexors, affections of other muscles, eye symptoms, absence of sphincter paralysis, later muscular atrophy; joint relaxation, cardiac palpitation, gastric weight and discomfort, and finally œdema. The great danger always present in this disease is sudden heart failure.

On the Examination of Sick Children.—L. Symes recommends the following routine: Facies, head, frame, bones and joints, reflexes, eyes, glands, abdomen, heart, lungs, spine, neck, mouth, and nervous system. We frequently make mistakes, he says, not because we do not know, but because we do not examine, and this is eminently the case in diseases of children. Under each of the above headings he mentions the various abnormal conditions to be looked for.

Hospitals; their Origin and History.—R. Dalton gives a historical sketch of the establishment of hospitals and their characteristics in the early centuries.

Zeitschrift für klinische Medicin, Vol. xxxix., 1900.

Excretion of Pepsin in Diseases of the Stomach.—Roth concludes that: (1) In private practice Mett's method is most practical for quantitative analysis of pepsin; (2) the variations in excretion are as great normally as that of hydrochloric acid; (3) examinations must be conducted under the same conditions of gastric contents; (4) some gastric juices contain more pepsin than the normal (hyperpepsia); (5) the greatest amount is found in gastric ulcer, the least in atrophy of the stomach due to chronic catarrh, carcinoma, or neurosis.

Transitory Spinal Paralysis.—L. Krewer states that clinically there exists a group of spinal paralyses which remind us of acute myelitis, which differs from it pathologically and anatomically. Hence they must be excluded and labelled as transitory spinal paralysis. These paralyses occur as a rule suddenly without any apparent cause and without previous predisposition. Sensory disturbances are entirely absent; painless muscular twitchings are observed in the paralyzed limb, and trophic disturbances are apparently wanting. In a few days the condition improves first in the paralyzed extremities, later in the bladder and rectum. The entire condition lasts from one to two months.

Changes in the Central Nervous System in Leukæmia.—E. Bloch and Hans Hirschfeld say that in leukæmia lymphomatous masses in the form of heteroplastic tumors occur in the meninges; symptoms of compression may appear or there may be no clinical evidence of the existence. Leukæmic cerebral hemorrhages are not uncommon: these may be of various sizes. Degenerative changes in the spinal cord are rare, though they do occur. A pure leukæmic infiltration may take place within the spinal cord.

Chronic Myocarditis and Cardiac Aneurism in Childhood.—Paul Rosenstein gives the history and post-mortem findings of a case of chronic cardiac aneurism in childhood and its very probable connection with tuberculosis.

Glycolysis.—F. Umber concludes that the rôle of the pancreas in diabetes is to-day just as indefinite as in the days of Mering and Minkowski. The article presents a series of careful tables and experiments.

Monatsschrift f. Geburtsh. und Gynäk., January, 1900.

Ovariotomy in the Schauta Clinic.—Oskar Bürger discusses ovariotomy very thoroughly, basing his conclusions on the observations of three hundred and ninety-four cases. He describes both the abdominal and vaginal methods, comparing their respective advantages, and believes the former to be advisable in case of adhesions, intraligamentary position of the tumor, twisted pedicle, or malignity, while in simple, benign growths the vaginal route is preferable.

Peripheral Tubal Sacks and their Significance in the Etiology of Tubo-Ovarian Cysts.—Edmund Waldstein explains these sacks as cystic growths which have developed at the ends of the tubes. They are enveloped by a connective-tissue wall and contain either serous or sero-purulent contents. The tube opens into it by its fimbriæ. These sacks have a very important influence on the development of certain tubo-ovarian cysts.

Report on Cases of Prolapse-Operation Performed in the Schauta Clinic with Especial Regard to the Lasting Results.—H. Schmit carefully tabulates these cases of prolapse operations, which fall into the following groups: (1) Vaginal total extirpation; (2) vaginal hysteropexy; (3) abdominal hysteropexy.

Artificial Premature Labor and its Final Results.—Ludwig Skovscheban reports that of thirty-three mothers only two died, or six per cent. One was a case of paratyphlitic abscess, so if this was not counted the deaths would be three per cent. There were thirty-four children born, twenty-seven of whom were living, or 79.4 per cent.

Contribution to the Therapy of Extra-Uterine Pregnancy.—Otto Th. Lindenthal thinks operation is indicated in all cases of uninterrupted extra-uterine pregnancy; in all cases in which through abortion or rupture a dangerous hemorrhage takes place, or when as result of infection fever and septic appearances exist.

The End-Results of Operative Treatment of Retroversio-Flexion of the Uterus. — Josef Halban gives the results of the three methods of operation as follows: Ventrofixation gave the best, 87.5 per cent.; vagino-fixation, eighty per cent.; vaginal shortening of the round ligaments, seventy-six per cent.

A New Method of Internal Measurement of the Living Woman.—Julius Neumann and Hugo Ehrenfest describe their method and instrument for measuring the pelvis. This latter they call the pelvigraph; it consists of two parts, the indicating arm and the exploring arm.

Clinical and Anatomical Contributions to the Question of Complete Tubal Abortion.—Ludwig Mandl, at the close of his dissertation on this subject, quotes Schauta's opinion that the abdominal method is pre-eminently the best in the operation for extra-uterine pregnancy.

Contribution to Surgery of the Ureter.—E. Wertheim declares that it is more difficult to obtain sufficient material to close old ureteral fistulæ than recent ones. In cases in which the defect cannot be repaired on account of lack of material, nephrectomy is necessary whether the kidney be sound or not.

Determination of the Pelvic Inclination in the Living Woman.—Julius Neumann and Hugo Ehrenfest give a diagram and cuts to describe their instrument, the kliseometer, which consists of a rigid bow. One end carries the indicator, and rests against the back, while the other marks a point on the symphysis.

Indications for Cæsarean Section.—Eduard Frank says that Cæsarean section is undoubtedly the easiest cœliotomy, and he adds that it is the duty of every obstetrician to be able to define his position in the case of perforation of a living child.

Decidual Polyp of the Uterus.—Fritz Hitschmann describes a tumor which came away spontaneously at the normal end of an eventful pregnancy. It consisted almost entirely of glands. It had no connection with the chorion.

Manual Treatment (Thure-Brandt-Schauta) in Gynæcology.—Oscar Piering writes of the efficacy of massage in gynæcological affections. He speaks also of the good results of the manual treatment of floating kidney.

The Anatomical Proof of Loss of Virginity.—Albin Haberda declares that in some cases the elasticity of the hymen preserves its integrity after coitus. In other cases there are scars left which constitute an undeniable proof.

Emphysema of the Uterus and Gas-Sepsis.—Josef Halban states that the histological examination of the case under his observation showed the chief changes to be necrosis of the uterine musculature with an absolute lack of inflammatory infiltration.

Researches Concerning Tuberculosis of the Female Sexual Organs.—Lucius Stolper declares that the diagnosis of genital tuberculosis is very difficult. The subjective symptoms are often slight or wanting altogether.

Melanosarcoma of the Female Pudenda.—Franz Torggler reviews the literature of this subject, and cites twenty cases. As to age, three-quarters of the cases observed were after the menopause. The malignancy of the disease is frightful.

Information concerning Carcinoma Psammosum of the Uterus.—H. Schmit gives an account of this tumor, which is characterized by its calcareous concretions. Its metastases also possess this peculiarity.

Contribution to the Theory of Fetal Cystic Kidney.—Sigm. Mirabeau concludes that the fetal cystic kidney is not very different from that of the adult.

Diseases of the Pericardium and of the Cardiac Vessels.—By G. Strube-Bremen. A review of recent advances.

Die Therapie der Gegenwart, January, 1900.

Treatment of Carcinomatous Œsophageal Stricture with Permanent Sounds.—H. Curschmann states that when carcinomatous stricture of the œsophagus renders deglutition difficult the regular daily passage of a tube is indicated, and feeding occasionally through it maintains the strength and nutrition. Gradual dilatation is not productive of much good in carcinoma. Permanent sounds are advisable only in the case of strictures situated in the middle or lower third; in strictures high up, surgical intervention is more beneficial. If the sound is well placed, feeding is easy, provided we use only fluid and semi-solid food.

Castration in Tuberculous Epididymitis.—E. Albert says that castration is contraindicated, because many patients live in comparatively good condition for many years with a tuberculous testicle, and also because despite double castration the tuberculous process is not stopped. If patients desire operation, incision of the nodules with subsequent curettage is all that is necessary.

Observations with the Stomach Tube in Infants.—O. Heubner demonstrates his method of determining the motor power of diseased stomachs; this also gives a clew as to the intestinal function. The tube is mainly useful for the removal of stagnating and decomposing contents, in cases of acute dyspepsia, chronic gastro-enteritis, pyloric stenosis, etc.

Observations upon the Therapeutic and Diagnostic Value of the Old Tuberculin.—A. Neisser presents his experience in cutaneous tuberculosis. If a typical local reaction occurs after tuberculin injection, then tuberculosis exists, and when it is constantly absent after a given dose, tuberculosis does not exist.

A Rare Operation.—Under this title, J. Hirschberg describes with illustrations a magnet operation for the removal of an iron fragment from the vitreous humor.

Annales de Dermatologie et Syphiligraphie, Dec., 1899.

Hyperkeratosic Interdigital Eczema.—W. Dubreuilh describes a chronic dermatosis of which he has seen four examples, the histories being given. The interdigital spaces of the toes are chiefly affected, but it may occur upon the hands. The skin between the toes is covered with a shining white, thickened, horny layer, which is detached in layers. There is not much pain or itching. Excessive sweating is not noted, though the macerated appearances would suggest hyperidrosis as one of the causes. Treatment is unsatisfactory; but ichthyol in alcohol has caused improvement, and chrysarobin ointment has been used with some success.

Treatment of Ulcer of the Leg.—Yaroslav Bukovsky has experimented with the products of the pyocyanic bacillus. In one hundred cases complete cure was effected in a relatively short time, when other measures had failed. Compresses wet with the toxin are changed two or three times daily. The beneficial action is shown by the rapid cleansing of the ulcer, epidermization, and healing with a solid cicatrix more quickly than by other forms of treatment.

Annales de Gynécologie, January, 1900.

So-Called Therapeutic Fœticide.—Pinard believes that the practitioner has no moral, legal, nor scientific right to practise embryotomy on a living child, and that to sacrifice a child in the mother's interests is a legendary form of practice which ought to disappear with other myths. The decision of life or death to the child does not belong to any one, and the doctor's only right of decision relates to the choice of the operation to be performed. A physician must always endeavor to save life, never to take it.

The Practice of Obstetrics.—F. J. Herrgott reviews a recent work by Henri Varnier, which he says is so truly descriptive that in reading it one truly seems to be present at a labor.

The Value of Oxygenated Water in Uterine Hemorrhage.—Dr. Platon has used this remedy successfully, when ergot and ergotin, hot injections, and tampons with the perchloride of iron had failed.

Annales de Méd. et de Chirurgie Infantiles, Jan. 1, 1900.

Contribution to the Study of Malignant Tumors of the Kidney in Children.—P. Sorgente says that the preponderance of the round-celled variety of sarcoma explains the rapid development of the majority of renal tumors in children. Epithelioma is very rare. Renal tumors are generally primary growths. They are almost always unilateral, and the right seems more often affected than the left. The kidney is the organ in children most frequently attacked by malignant neoplasm. As to age, the first year of life furnishes the largest number of examples. Sarcoma in all its varieties is the most usual form. In summing up the results of operated cases, it is found that death by operation is frequent, recurrence is very frequent, and a definite cure is exceptional. However, the results of recent operations have been happier than the earlier ones were.

Eczema in Young Children.—E. Périer gives the history of an eczematous child who serves as a type in this trouble. Baths were stopped, sponging with tepid marshmallow water being substituted. For three days local compresses of cold boiled water were applied, covered with oiled silk. After three days the child was washed in olive oil, and then a coating of zinc paste containing a little menthol was applied to diminish the itching. Internally it was given from two to three glasses of hot boiled water in which was a small pinch of bicarbonate of soda.

Congenital Ocular Lesions in a Child Born of a Mother Attacked with Typhoid Fever toward the End of her Pregnancy.—A. Antonelli cites a case of optic neuritis together with chorio-retinitis in a child whose mother had typhoid fever in pregnancy. He states that this disease often provokes profound ocular complications.

Contribution to the Study of Paroxysmal Hæmoglobinuria.—R. Guita and C. Valvassori Peroni, in reviewing a case of this kind, think that atmospheric influence played considerable part in the causation of this curious malady.

Russki Arkhiv Patologii, etc., December 31, 1899.

Chyluria Nostras and its Causes.—V. E. Predtechenski says that chyluria is not an exclusively tropical affection. About twenty cases are on record in persons who had never been outside of Europe. The author reports the first case seen in Russia. Examination of the urine showed the presence of large numbers of small lymphocytes which could have escaped only through some solution of continuity of the walls of the lymphatics. The eggs of tænia nana were also found in the urine. The parasites which cause tropical chyluria are filaria sanguinis hominis and distoma hæmatobium; those accused of inducing chyluria nostras are eustrongylus gigas and possibly tænia nana. Among the causes which may provoke non-parasitic chyluria are probably tumors, peritoneal adhesions, and other pathological processes which may obstruct the lymphatic vessels and produce stagnation of the chyle. The author obtained favorable results in his case by the administration of gr. xv. of gallic acid three times a day.

Meteorism in Typhoid Fever and its Treatment.—V. E. Chernoff says that this occurs under two conditions: (1) When there is greatly increased formation of gas in the intestine; and (2) when there is atony or paresis of the intestinal wall, a result of local poisoning of the nervo-motor apparatus by the products of abnormal fermentation of the intestinal contents. Inflammation of Peyer's patches and of the mucous tunic in general is the usual cause of the abnormal fermentation, and often the extent and depth of the inflammation occasion a localized peritonitis, which in turn increases the meteorism. By limiting the inflammation by means of the local application of cold, reducing by the same means intestinal fermentation, and exciting the peristaltic movements, we better and more speedily succeed than in any other way in overcoming the meteorism with its attendant dangers.

Etiology and Pathological Anatomy of Werlhof's Disease.—V. N. Konstantinovitch reports a case of purpura hæmorrhagica occurring in a laborer, eighteen years of age. At the autopsy he found hyperplasia of the aorta, old tuberculous lesions of the bronchial glands, pigmentation of Peyer's patches and the solitary glands (probably due to a former typhoid fever), small spleen, hemorrhages in various tissues and organs, and anæmia. Bacteriological examination was negative. Histological examination showed fatty degeneration of the endothelium of the capillaries in all the organs—even in those in which no hemorrhage had occurred, as the brain for example. The author had no theory as to the cause of this fatty degeneration of the capillary vessels, upon which the petechial eruption depended, but thought there was possibly some form of auto-intoxication.

Myoœdema and its Pathological Significance in Mental and Nervous Diseases.—N. Bernstein has found this phenomenon present in twenty-eight cases of general paralysis, in forty-four out of forty-six cases of precocious dementia, and in eight of idiocy, but in none of five cases of mental confusion of Meynert, or of eleven of mania and melancholia. He found it also in all cases examined of epilepsy and cerebrospinal syphilis, and in three out of four cases of tabes. He believes that there is in these affections a special form of auto-intoxication which acts directly upon the muscular tissue.

Terpinol in Hæmoptysis.—Th. G. Yanovski asserts as the result of his experience that terpinol is useless in hæmoptysis from pulmonary congestion, but renders signal service in many cases of hemorrhage dependent upon tuberculosis. The good effects were usually noted after from five to seven doses of three drops each every two hours.

The Influence of the Toxins of Tetanus and Diphtheria on Metabolism.—L. Sverzhevski studies the alterations in the gaseous and nitrogenous exchange produced in dogs and rabbits by the action of the toxins of tetanus and diphtheria.

Correspondence.

THE STUDY OF MALARIA IN ROME.

(From an Occasional Correspondent.)

THE ÆSTIVO-AUTUMNAL PARASITE IN MAN AND THE MOSQUITO—THE ROMANOWSKY STAIN—MALARIA IN THE CAMPAGNA.

Professors Bignami and Bastianelli do most of their work on the malarial organism in the laboratories of the Hospital Santo Spirito, on the left bank of the Tiber, and it is worth a good climb up that old spiral staircase to get a view of the mounted specimens they are studying at present.

One morning last week I had the pleasure of going over them with the professors, who are most enthusiastic in their research and who are doing some splendid work here. At present they have complete sets of mounted specimens showing the morphology of the parasite of the æstivo-autumnal variety—the only one which they have yet been able to follow through its entire life history; that is to say, from the time it is taken into the human blood, through its various cycles there with which we are all familiar, until it is taken into the stomach of the mosquito; its rest in the stomach walls, and thence to the salivary glands, ready for transmission to man.

Among the most interesting slides are those showing the parasite in the stomach walls of the Anopheles claviger, usually lying in the muscular layer between the fibres, but one very pretty specimen showed the organism resting in the mucous membrane between the epithelial cells. Other slides demonstrated very clearly the sporulation of the organism and the fecundation of the female.

The Romanowsky method is the only one used in staining specimens, and Professors Bastianelli and Bignami consider it the only one whereby it is possible to demonstrate the structure of the malarial organism. As they use it, it is very simple, consuming little time and yielding most excellent and certain results. They had the same difficulty with it at first that we have had in America, but they find no trouble whatever if they use the medicinal methylene blue and the eosin B (brom-eosin). The proper solutions are:

I. Methylene-blue saturated solution (10 gm. methylene blue added to 100 gm. of water): keep for twenty-four hours at a common temperature—near 20 C.—and filter. The filtration fluid is immediately ready for use.

II. Eosin. 1 gm. of eosin B to 100 gm. of water; filtration is not needed.

Staining: Add 2 cm. of the methylene-blue solution to 5 cm. of eosin solution: place in a proper glass, and, the slide having been prepared in the usual way and fixed in absolute alcohol for twenty-five minutes, stain for from thirty minutes to one hour. It is useful to employ the glass recommended by Lieman. Professor Bastianelli says that by following these directions one is sure to have good results with every slide.

The laboratory boy here is popularly known as "Romanowsky," from the amount of this stain he is employed in making up, its preparation being entirely left to him.

Stained in this way the chromatin elements stand out clearly and sharply, excellently differentiated, and the structure of the nucleus and its nucleolus (as Professor Bastianelli considers it should be called) shows as perfectly as could be desired for purposes of study.

There are abundant opportunities here for the study of malaria in all its manifestations, both clinically and in the laboratory, and the physicians and directors of the laboratories are most hospitably inclined toward students from all countries, particularly America. The pernicious forms of the disease abound, and the hospitals get a very large share of the neglected cases. The peasants of the Campagna suffer most of all, as is natural from their mode of life. A straw hut without a floor except that afforded by Mother Earth, generally built on the lowest possible level for protection in winter, is the abode of the average farmer or shepherd. They go through the summer with their regular or irregular chills as the case may be, accepting them as part of their lives. This goes on until the malarial cachexia or a particularly heavy infection in their debilitated condition makes it imperative to visit the Sancto Bambino, who is the oldest physician in Rome—being a wooden doll crowned at the Vatican, supposedly possessed of wonderful power of healing. When this treatment fails the patient is brought to the hospital, and quinine and arsenic get their turn. Quinine subcutaneously is the method generally adhered to in Rome. It is rarely given by the mouth. The results are excellent, even in the very bad cases, but of course there is also plenty of opportunity to study post-mortem the effects of the malarial infections in a country where the mosquito is rampant and the average hygienic conditions so bad as they are in Italy.

THE STATIC INDUCED CURRENT AND DR. ROCKWELL.

To the Editor of the Medical Record.

Sir: It is impossible to confine Dr. Rockwell with logic or facts; cuttlefish-like, he scurries off in a cloud of speculative verbiage. In your issue of December 23d he volunteered an entirely gratuitous attack upon me, my methods of treatment, my cases, deductions, and inventions. In your issue of January 6th, I perforce answered his letter, ignoring, however, as trivial everything except the one question of the invention of the static induced current. On this point he had stated that he had in his possession "an old book in which is given both in description and illustrative detail what is now called the static induced current." Now here was a definite assertion. I challenged him to prove it, and even went further and said that if he would prove it, I would withdraw any claim to originality in the invention I had ever made. But what is his reply? We have it in your issue of January 20th. Not a scintilla of proof of his position is brought forward; not a word to substantiate his charge; not a line is quoted from his ancient book. And simply because there is not a word in this book to show that the ancients ever knew of "what is now called the static induced current." Having no proof to offer of his initial assertion, he shifts his ground and claims that "the principle upon which the whole subject is based" is given in these books. He changes his base from a specific assertion to a glittering generality. "It needs but a glance," he writes, "at these old illustrations to make it evident that these more recent ones of Dr. Morton are in their essential characteristics absolutely the same, and that from the arrangements represented by these illustrations the spark-gap *could* be so adjusted as to produce the so-called static induced current with the power to induce continuous muscular contractions." I have underscored the word *could*. This single word betrays Dr. Rockwell and all his sophistry.

And such is the specific reply which readers of the Medical Record are asked to accept. "The ancients could have produced the static induced current." It takes patience to say, in reply to such childishness, that no doubt they could have done so, but that they didn't do so. On lines of argument of this sort, one could prove that every discovery and invention is ancient or has been anticipated by some one else. The ancients had zinc and copper and sulphuric acid, and water and receptacles, and they could have adjusted these things so as to produce a galvanic current; but they didn't, until Galvani and Volta did it. They had frictional electric machines, and Leyden jars, and sparks and spark-gaps, and even adjusted these parts to give measured and graduated individual shocks one by one to the patient, but they never used these parts nor these adjustments to produce any sort of a current. Of course the principle upon which the whole subject is based is in these books and in many technical books. I never said that it was not, nor that I discovered it. But, utilizing the principle, I did discover and produce currents before unknown and unrecorded. To make an invention or to discover something does not by any means require a very big jump. Reiss invented the singing telephone, in which the electrodes just failed to touch, and Bell by a turn of a millionth of an inch of a screw, thus bringing the electrodes into actual and continuous contact, invented the speaking telephone. Reiss didn't do quite enough, little as what he failed to do was, and, similarly, the ancient electricians might or could have invented or discovered the static induced current, but they didn't.

According to my critic's line of argument, Reiss was the inventor of the speaking telephone and not Bell. The instrument and the adjustments, in short "the principle upon which the whole subject was based," were there, but Reiss unfortunately failed to make his instrument speak, just as my critic's ancients had machines, spark-gaps, and "arrangements," but failed to produce a static induced or any other current, and made no mention of the subject of currents. These ancient writers on electricity described every effect of their administrations and discoveries with the minutest detail. One is constantly surprised at the accuracy of their descriptions. Is it to be supposed for an instant that an effect like the static induced current, so different from anything they do record, would not have been recorded? It is incredible. But, incredible or not, they didn't record it, and that ends honest and sane discussion. For what the ancients might have done or could have done does not concern us. They might have invented all the coming inventions of the twentieth century; but we know they didn't. Dr. Rockwell would have us believe that they universally and by a sort of conspiracy refrained from describing a thing so salient as a tetanizing effect upon a muscle, and a method and the current which produced this effect.

Now a word more to my assailant, since he says I "divert attention from the main points of contention."

First, "he" (the writer) "has persistently exploited his own originality at the expense of the originality of others." As to the originality of others, this is what I am still waiting to hear about from Dr. Rockwell. Practically no one disputes my humble claims. As for persistence, it is indeed a pity to fight persistently for one's own. In this respect, I am reminded of the doggerel:

> "It is a very good world to live in,
> To lend, or to spend, or to give in;
> But to beg, or to borrow, or to get a man's own,
> It is the very worst world that ever was known."

Second, and finally, "he" (the present writer) "makes extravagant and utterly unjustifiable therapeutic claims." All I can say to that is that it is a matter of opinion, and furthermore, that I do not agree with my very amiable critic. He reminds me of an anecdote. After the entire Copernican and Newtonian philosophy of the rotation of the earth around the sun had been explained to Brother Jasper, he walked off, we are told, triumphantly remarking, "But, after all, the sun do move." Now, to tell the truth, I never did expect to have Brother Rockwell understand what I write. Perhaps there are more things in heaven and earth, and, say, in electro-therapeutics, than Brother Rockwell's philosophy dreams of.

William J. Morton, M.D.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From Our Special Correspondent.)

When the attempt of Sir Redvers Buller's relieving force to get to Ladysmith by turning the right flank of the Boers, or by carrying their intrenchments on that side, failed, after the previous failure of the point-blank attack at Colenso, it became at once apparent that the plight of Ladysmith was very serious. Even before this reaches you, it is possible that the beleaguered city may have fallen. If Sir George White is forced to capitulate, the blow to the English empire will be comparable only to that sustained a hundred and twenty years ago (or so) by the fall of Yorktown, and there are some who think that the consequences will be no less far-reaching. The present population of Ladysmith is over ten thousand; there are a good many women and children, and a very large number of horses, and the accommodation generally is unfitted for such numbers. The water supply is imperfect though not actually scanty, and it is generally believed that, if the city has to surrender, it will be because of the ravages of typhoid fever, and not because either of scantiness of supplies or ammunition or loss of courage. By the third week in January the fatal cases of typhoid fever amounted to ten per diem, and although this figure afterward abated a little, every day of confinement, under circumstances of such bitter chagrin and apprehension as the garrison are now undergoing, must tell against their *morale* and render them less able to resist the attacks of disease. If the city is to be saved, it must be saved soon.

A New Hospital Ship.—Up to the end of the second week in January, two thousand men of all ranks, officers, non-commissioned officers, and privates, had been admitted to the two big general hospitals at Wynberg. With the unfortunate turn for British interests that affairs have so far taken, it became clear that another hospital ship would be wanted, and one of the transport vessels belonging to Sir Donald Currie's line, the *Lismore Castle*, was chosen for conversion. The tonnage of the *Lismore Castle* is 4,000, and now that she is a hospital ship, she can accommodate two hundred and fifty sick. On the main deck are situated an officers' ward, an orderly room, an operating-theatre, fifteen convalescent officers' cabins, a dining-saloon, and three bath-rooms. On the lower deck there is accommodation in four wards for two hundred and twenty-five men. Each ward runs from side to side of the ship, and is ventilated by electric fans. The cost of this complete conversion of a mail steamer employed as a transport into a hospital ship was considerable, and the work was done by the admiralty at Durban, with some civilian assistance, in four and a half days. The new hospital ship is under the command of Dr. Brodie, a civil surgeon, who is assisted by three other civil surgeons—for the supply of officers of the Royal Army Medical Corps has run short—and who has under him one army nursing-sister, four civilian nurses, thirty civilian male medical attendants, two dispensers, and one sergeant with nine privates to be used as fatigue men or guards.

Some Remarkable Recoveries.—The list of remarkable recoveries from injuries, which by all the accepted canons of surgery should have been fatal, is very large; indeed it is becoming abundantly evident that at one thousand yards the modern rifle bullet makes a wound that is serious only if the most vital structures are perforated, and not always then. The wounds of entrance and exit are small, and the track is marked by none of the rending, splintering, and crushing that were wont to make of the old bullet wound so serious an affair. Accounts have been given of the following extraordinary recoveries, and they are only a type of others every whit as wonderful:

A man was shot below the left clavicle. The bullet emerged two and one-half inches above the angle of the left scapula, *i.e.*, at the level of the ninth rib. After some hemorrhage, there was an empyema, but the patient recovered.

A man was shot from behind through the right sacro-iliac synchondrosis. The bullet emerged halfway between the anterior superior spine of the ilium and the ninth costal cartilage, wounding the cæcum in two places. There was extravasation of fæces, but the patient recovered.

A man was shot one inch above the right clavicle in the line of the posterior border of the sterno-mastoid muscle. The bullet emerged at the corresponding spot on the left side. He could not swallow or speak when picked up, but gradually his symptoms subsided, and no complication ensued.

A man was shot an inch to the right, and the same distance above the symphysis pubis. The bullet emerged through the right buttock two and one-half inches external to the anus. He ran one-third of a mile, completing a long charge, after being wounded, and recovered without any serious symptoms.

A man was shot half an inch external to the posterior superior spine of the left ilium. The bullet traversed the stomach, and emerged at the ensiform cartilage. The wound healed by first intention.

A man was shot in the right side of the nape of the neck, at the level of the third cervical spine. The bullet emerged at the inner canthus of the left eye, loose portions of ethmoid being picked out of the wound. He recovered without symptoms.

These are only specimens of the cases among both the Boers and the British, which have been recorded by Sir William MacCormac and Mr. Treves, whose respective letters in the *The Lancet* and *British Medical Journal* have done great work in restoring in England the full confidence in the work of the Royal Army Medical Corps which the supercilious attitude and parsimonious behavior of the War Office toward that branch of the service had done so much to destroy. At the present time, the R. A. M. C. is practically the only department of the British army against which serious charges of failure cannot be levelled.

The Heroism of a Member of the R. A. M. C.—After the battle of Colenso—the first unfortunate attempt to relieve Ladysmith—an officer of the Royal Army Medical Corps, Major Babtie, distinguished himself by a feat of courage and daring which it is to be hoped will be recognized by the military authorities. The R. A. M. C. already possess more Victoria Crosses than any other branch of the service, and it now seems possible that Major Babtie's name will be added to the list of holders of this much-coveted honor. During the thickest of the fight Major Babtie rode into the donga — the dried-up watercourse in which the British losses were most severe, and where Colonel Long's guns had to be abandoned—and remained with the wounded through a hail of bullets, doing what he could for them. Among others whom he attended under these terrible circumstances was Lieutenant the Honorable Frederick Roberts, the only son of Lord Roberts, V.C., the commander-in-chief of the British army in South Africa. Major Babtie's horse was killed under him, but he remained in the donga until firing ceased, doling out minim doses of water from his water bottle, and rendering such first aid as was possible. It was extremely sad that Lieutenant Roberts' life could not be saved, but he was shot in the forearm, wounded in the knee by a shell, and had in addition a perforating wound of the abdomen. When Major Babtie brought him back, he was pulseless, and died without rallying. He had behaved with conspicuous gallantry throughout the engagement, and had been recommended for the Victoria Cross, a decoration which his distinguished father gained in 1858.

OUR LONDON LETTER.

(From our Special Correspondent.)

INFLUENZA — OPHTHALMOPLEGIA IN TABES AND IN GRAVES' DISEASE—TETANUS TOXIN—PAROXYSMAL HÆMOGLOBINURIA—MALIGNANT GROWTHS OF THYROID—ARTHRECTOMY OF KNEE—DUBLIN MORTALITY —SALVATION ARMY SHELTERS.

LONDON, January 19, 1900.

INFLUENZA has made a further advance all along the line. The deaths from the epidemic reported last week rose to 340. The deaths from all respiratory diseases, which I last week said had risen to 1,221, fell to 994, but that is 260 above the average for the decade. Of course with so many fatal cases the number of mild ones and even severe ones that result in recovery is enormous, and the widespread sickness keeps the doctors very busy. Many are themselves victims. London's total mortality last week was 2,930, being 642 above the average of ten years. The deaths exceeded the births by 164. The epidemic seems to have swept our island almost from south to north. In some of the southern towns it is already abating, and we are hoping London has seen the worst. The following death rates for the last two weeks are significant: Birmingham, 27.0, 33.6; Brighton, 44.9, 28.6; Croydon, 40.5, 37.4; Liverpool, 34.4, 34.6; Norwich, 32.7, 43.6; Nottingham, 40.8, 44.9.

Ophthalmoplegia often has a certain association with tabes; at any rate it has frequently been observed to precede ataxia. Such cases naturally come first under the notice of oculists, and may subside long before signs of tabes appear. Dr. Guthrie related a case at the Harveian Society which he had had under observation some six months. At first there was doubt as to the diagnosis, but at length it became obvious.

Mr. Juler, president, and Dr. James Taylor agreed as to the frequency of ocular paralysis in early tabes. The paralysis is usually transitory and the knee jerks still present.

Cases of ocular paralysis occurring in Graves' disease have been recorded by several observers, and Ballet's monograph on the subject makes three groups, viz., ophthalmoplegia with Graves' disease; with hysteria; with both Graves' disease and hysteria. A case observed by Dr. Warner was related at the Medico-Chirurgical Society on the 9th inst., and reference was made to another case brought forward in 1882, the sequel of which is given in Bristowe's "Diseases of the Nervous System."

Mr. James Berry said he thought hysteria played a very important part in these cases, and made some interesting remarks on the pathology of Graves' disease. He held the theory of its sympathetic origin to be entirely erroneous, and pointed out that experiments on animals in this domain must be very fallacious. One advocate of division of the sympathetic had said he would only employ it when the cornea was in danger of sloughing, but there was one case in which it had sloughed after the operation. There were still men who believed exophthalmos to be due to dilatation of blood-vessels behind the globe; but the conjunctiva was not more vascular than normal, which it is whenever congestion of the orbit can be proved to be present.

Mr. Foulerton and Dr. Campbell Thomson communicated to the Medico-Chirurgical Society at the last meeting the results of an investigation into the nature of the changes in the nerve cells of the cortex produced by the tetanus toxin. They had carried out a number of experiments in which the cerebral cortex was examined after the inoculation of tetanus toxin in rabbits, guinea-pigs, and mice, the doses being varied and the animals killed at different periods after inoculation. Certain definite histological changes had been found in the motor cells, though the appearances varied somewhat with differences as to dose and time. The research had been conducted more particularly with reference to the nerve cells of the motor area of the cerebrum, but evidence had been obtained that similar changes occurred in cells of other portions of the cerebral cortex and also in the cerebellar cortex. The changes were readily distinguished from those produced by other bacterial toxins, and the motor disturbance in tetanus seemed to be due to these changes; so that the incubation period must be regarded as the time required for sufficient toxin to be taken up by the blood and fixed in the cell substance.

Mr. Foulerton in reply to questions said every care had been taken to exclude fallacy from post-mortem changes or those which might arise from pyrexia. As to the latter point, the temperature, taken three times daily, had never risen more than 1.5° F.

A case of paroxysmal hæmoglobinuria in a girl, aged six years, was shown at the Clinical Society by Mr. Lunn. She was the tenth of twenty-four children, of whom fourteen are living. From the age of one year she had at intervals passed urine containing normal red cells. The proportion of red to white in her blood is about half normal. A sister had interstitial keratitis.

Mr. Spencer referred to a case in a boy he had formerly shown, and remarked that in early life many such cases ended in uræmia or apoplexy.

Dr. Voelcker said that, as in this case, there was usually evidence of inherited syphilis. In one case he had found a history of acquired syphilis. He had noticed an undue tendency to cohesion of the red corpuscles, forming snake-like coils, the corpuscles themselves being elongated, lemon-shaped. Dr. Sutherland remarked that paroxysmal hæmoglobinuria and albuminuria had been observed to alternate. Excess of oxalates was often present and persisted some time after the hæmoglobinuria had ceased.

Mr. Lunn said oxalates had been noted in his case, but the intermediate urine seemed normal. He added that the girl usually had a rise of temperature with chill and collapse when an attack was imminent. Her health seemed good between the attacks.

Among other interesting cases shown at the same meeting was one of malignant growth of thyroid in a woman aged fifty-eight years, supervening after nine years' enlargement which had necessitated two operations on account of pressure on the windpipe. Mr. Barker remarked on this that malignant growths of the thyroid were usually very chronic; one of his had lasted eighteen years. Mr. Symons said one of his lasted over ten years, but another only twelve months.

Mr. Eve showed a girl, aged thirteen years, on whom he had performed arthrectomy of the knee for tuberculous disease. The semilunar cartilages were removed and one crucial ligament had to be divided, but was afterward refixed to the bone. The lower end of the condyle, being ulcerated, was scraped. The result was free movement almost to a right angle. Mr. Eve was congratulated on this. He admitted the case was subacute, and when there were much ulceration and caseation he would not attempt so much. He hoped to show the patient again later on.

The death-rate of Dublin has lately been so high that the lord-lieutenant proposes to hold an inquiry into its cause by a committee on which the local government board, the College of Physicians and Surgeons, and the corporation of the city shall have representatives. *The Medical Press and Circular* has called attention to the high mortality again and again, attributing it largely to a disgraceful condition of the poorest tenements, and urging the corporation to provide improved dwellings on sites said to be obtainable at low prices.

The Queen's Bench has given a decision on a case stated by the chief London magistrate, which will bring the Salvation Army shelters under sanitary supervision. No doubt the night shelters have been a benefit to some of the poorest, and no one imputes any but good motives to General Booth and his followers. But very few will defend him for engaging in obstructive litigation for the sake of defying the sanitary authorities. It was a gross blunder in tactics, and there was no justification for thus using the funds of the army. The shelters will now come under the common lodging-house acts.

SMALLPOX IN THE PHILIPPINES.

To the Editor of the Medical Record.

Sir: Although I only see a medical journal here occasionally, I have been struck with the widespread occurrence of variola throughout the United States during the last year, and it seems to me that our relations with these islands have probably had something to do with its spread. Smallpox may be truly said to be universal here among all classes of natives, as is attested by the fact that nearly every one is more or less pockmarked. I doubt if many natives reach the adult age without having had an attack. So common is it that the people take it as a matter of course and make no effort to guard against it in any way. Now, these people have their own looms in their homes. and they manufacture many varieties of fine "Josi" and "Piña" cloth, which are much sought after by American soldiers as souvenirs, and by them sent through the mails to their friends. When it is borne in mind that ten to twelve natives often live, sleep, and eat, and manufacture and store cloth all in one small, dirty room, the result is obvious; their cases of smallpox, leprosy, or any other illness are never isolated in the slightest degree. To illustrate, I recently had personal knowledge of the following incident: A native woman who had been in the habit of bringing specimens of "Josi" to the home of an officer for sale failed for a little while to come with her usual regularity; after a few days she did return, and when questioned as to her absence casually explained that she had been too busy with several cases of smallpox in her family! She, however, brought a goodly supply of "Josi" from the infected room! Besides this source of infection, the thousands of returning soldiers have all brought with them and scattered over the country souvenirs of one sort or another taken from these same places.

Charles F. Mason, M.D.,
Major and Surgeon U.S.V.

Iloilo, Panay, P. I., December 25, 1899.

Empyema of Tuberculous Origin, or from lung abscesses, is benefited by a surgical operation only to the extent of temporary relief.—Samuel C. Benedict.

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, January 15, 1900.

FREDERICK HOLME WIGGIN, M.D., PRESIDENT.

Secondary Osteoplasty.—DR. THOMAS H. MANLEY presented a patient illustrating what might be accomplished in some severe and complicated fractures by secondary osteoplasty. About fourteen months ago this man had been knocked down by a broken belt, and had sustained a fracture of the ulna in its upper third, and a dislocation of the head of the radius on to the acromion process. He had been treated at a hospital by an eminent surgeon for five or six weeks, and then had been treated as an out-patient for some time longer. The arm had remained practically useless, being insensible, cold, and wasted, and the fingers contracted rigidly so as to make a claw-shaped hand. Rather curiously he had been advised not to submit to further operation. He had, however, come to the speaker in the hope that a better functional result could be secured. This was two months ago. Dr. Manley had laid open the injured region and had resected the head of the radius, thus securing pronation and supination. The median nerve had been greatly reduced in size as a result of the compression to which it had been subjected. Within two weeks the man had been out of bed. Sensation had returned quickly, and mobility had rapidly increased.

Gangrenous Perforation of the Sigmoid Flexure.—Dr. Manley then presented a specimen removed from a man who had entered the Harlem Hospital with a history of having, in apparently good health, been suddenly seized with severe abdominal cramps, especially violent in the left iliac fossa. An enema had been returned with almost no result. On admission to hospital the same evening the man had been in a condition of profound collapse, and the abdomen greatly distended. On percussion, there was greater flatness in the left iliac region. A large oil enema had failed to move the bowel. He had then performed abdominal section, and at once a large quantity of soapsuds and sweet oil had gushed out. Examination showed a gangrenous perforation of the sigmoid flexure.

Large Omental Hernia.—Dr. Manley also presented a portion of omentum weighing twenty-seven ounces that he had removed in an operation upon an omental hernia. Three weeks before coming under observation, while lifting a barrel of beer, the patient had felt something give way, and had then become conscious of an enlargement along the course of the inguinal canal. The operator opened up the inguinal canal throughout its whole extent, and, after dragging out the mass of omentum, had divided it slowly, securing each vessel as it was cut. He had firmly fixed the stump at the external ring in order to secure good control of the parts in case of hemorrhage, and in the event of infection to make it extraperitoneal. The man had made a rapid recovery.

Fibroid Uterus.—DR. FREDERICK HOLME WIGGIN presented a fibroid uterus which he had removed a few hours before by the intraperitoneal method.

A New Method of Retroperitoneal Drainage of Pyosalpinx, with a Report of Five Cases.—DR. LEON F. GARRIGUES read a paper with this title. He expressed the belief that all pelvic suppuration should be drained through the vagina, vaginal drainage itself being almost free from danger to life. As a rule, after vaginal incision in cases of pyosalpinx the temperature dropped to normal, the pain ceased, and convalescence was rapid. On the other hand, after laparatomy in these cases there were often considerable shock and pain for a long period, and the patient remained in bed at least a month. It was not uncommon for a woman to be an invalid for the greater part of a year after such an operation. Then there was the danger of ventral hernia. It seemed to him irrational to ligate and excise a tube when the part left might contain virulent bacteria. Under such circumstances the patient might be worse after than before operation. Howard Kelly and others had advised puncture of the abscess and packing the cavity with iodoform gauze. This technique seemed to him faulty because he had seen serious hemorrhage follow this procedure. Moreover, the gauze packing was not only painful, but being compressed it failed to drain the cavity properly. It should not be forgotten that about half of all cases of pyosalpinx operated upon were found to contain virulent bacilli in the tube.

The Technique.—The technique recommended was as follows: An incision was made at the anterior vaginal junction, beginning behind the transverse line drawn through the cervical canal on the side corresponding to the pyosalpinx, and following the contour of the cervix for three-fourths of an inch. This incision extended through the thickness of the vaginal wall. The forefinger of the operator was next introduced through the opening and pushed upward. The peritoneum usually stripped readily from the uterus, and it should be stripped off gently until the origin of the Fallopian tube was reached. The tube should be opened at this point only if it was the prominent part of the sac. While an assistant pressed down from above, blunt scissors should be pushed into the pyosalpinx. With the finger a thorough exploration should be made, and then a T-shaped rubber drainage tube was to be inserted. The abscess should not be irrigated at the time of the operation for fear of a minute opening being made, and infectious matter be carried into the peritoneal cavity. As a preliminary step all cases were curetted. In all of the five cases reported the patients had been out of bed within a week after operation, and all had recovered completely. Four out of the five had been operated upon in tenement houses, and had received only unskilled nursing. This method of retroperitoneal drainage was not difficult of performance.

Another Method Preferred.—DR. RIDDLE GOFFE said that he was a persistent advocate of the vaginal route in attacking pelvic disease, and believed that no one was justified in doing a laparatomy until the effort had been first made to reach the disease within the pelvis by the vaginal route. He had never tried the method advocated in the paper, and could not speak of it critically until he had studied the details of the histories reported. He objected strongly to the opening up of the broad ligament for the purpose of reaching pus in the pelvis. This was a layer of cellular tissue unusually rich in lymphatic vessels, and there was danger of opening up a cavity filled with virulent pus and infecting this area. He was also opposed to the method described, for the reason that it was a temporizing measure. In cases of this kind a woman should not be subjected to more than one operation to effect a cure. It seemed to him preferable to open the pelvic cavity freely and ascertain the extent of the disease, and then radically treat it. His own method was to open freely into Douglas' pouch, and carefully explore the region. Later on he opened the anterior portion of the vagina, and brought down the uterus and its appendages through this vaginal incision. If the abscess was large it was necessary to puncture it and drain the cavity before delivering the uterus and its appendages in this way through the anterior fornix.

Previous to doing this the peritoneal cavity should be protected from infection by proper gauze packing. He never removed the appendages of both sides when it was possible to leave even a small fragment of one ovary. By leaving such a portion behind, the woman was relieved from many unpleasant nervous disturbances.

Dr. J. E. Janvrin said that his own practice had been to make a puncture through the posterior cul-de-sac, inserting a tube, and securing free drainage. He did not think that, as a rule, there was much danger of peritonitis from such an operation, and in the majority of cases it would effect a cure. The objections to Dr. Garrigues' technique made by the last speaker seemed to him important and valid, though he had not had any personal experience with the method. It seemed to him that the danger of such method was fully as great as from making the posterior opening. The method recommended by Dr. Goffe was certainly radical and thoroughly successful, as he could testify from personal observation. He did not feel disposed to criticise Dr. Garrigues' method until he had had an opportunity to observe its workings personally.

Dr. H. J. Boldt said that he too had had no experience with the method described in the paper, having been in the habit of employing the posterior incision. It seemed to him extremely difficult, if not impossible, to remove a pyosalpinx located high up in the pelvis in the manner described by the reader of the paper. One trouble was that these abscesses were usually sacculated; another was that the Fallopian tube was not very greatly enlarged in many cases, so that much difficulty would be experienced in opening and draining the tube. His own practice had been to open up the cul-de-sac widely enough to admit the hand, and so be sure that he was actually dealing with the Fallopian tube, and not with another collection of pus in the pelvic cavity.

Dr. Garrigues said that the objections made to his method seemed to him rather theoretical than practical. In every case the temperature had dropped to normal within a few days, and hence there was no reason to believe that the lymphatics had absorbed the poison. He had been using this technique for the past two years, and could speak confidently regarding the radical cure effected in at least two of the most difficult and severe cases. He made it a rule to explore the region with the finger to be sure that every portion was drained. All the cases in which he had operated in this way had been large pus tubes, and he could not say how the procedure would succeed when the tubes were quite small.

Strangulated Hernia; Some Practical Remarks Concerning its Diagnosis and its Proper Management.—Dr. Parker Syms read this paper. He said that the arrangement of the vascular system of the intestine was such that strangulation of only a small portion of the intestine led to the derangement of the blood supply to the whole bowel. The symptoms of strangulation were those of acute intestinal obstruction, and in no way resembled those of ordinary constipation. The more prominent symptoms were pain, tenderness, vomiting, obstipation, tympanites, local changes, disturbance of the pulse and temperature, a peculiar facial expression and mental condition. The pain usually radiated at first from the umbilicus, but afterward became general. Tenderness was accompanied by pain, and both continued until reduction had been accomplished, or gangrene had occurred. Sudden cessation of pain and tenderness without reduction of the hernia betokened gangrene. The vomiting was at first reflex; later on it became projectile, and was the result of obstruction of the intestine and interference with the waves of peristalsis. Obstipation was present from first to last. The tympanites increased until relief had been obtained. The local symptoms, aside from those of hernia, were those of acute inflammation, to which were added loss of impulse on coughing and loss of tympanitic resonance. The pulse became rapid, irregular, weak, and thready. The temperature was often subnormal from shock. When systemic infection took place the temperature was elevated. The facial expression was the drawn and pinched appearance characteristic of abdominal injury, and known as the Hippocratic face. The capillary circulation was always disturbed, as evidenced by pallor and slight cyanosis of the extremities. Shock was always present to a greater or less degree, and was an important clew to the correct diagnosis. Hiccough might come on at any time, or might be absent altogether. Strangulated hernia unrelieved always proved fatal; on the other hand, its early recognition and proper treatment almost always resulted in saving life.

Treatment.—Sometimes cold was applied to the part, the pelvis being elevated and food withheld for a short time in the hope that spontaneous reduction might take place; but this seldom occurred. The large mortality recorded against the surgery of strangulated hernia was entirely owing to the use of prolonged taxis, and the postponement of operation until a late stage. In no case could taxis be looked upon as free from danger, no matter how gentle the manipulations, and it should be unreservedly condemned. When the vomiting was persistent and severe, local anæsthesia was needed. It was his rule to administer a full dose of morphine and one ounce of whiskey, and then use cocaine locally in weak solution. After having made a free incision down to the sac, the dissection must be carried on cautiously. Having opened the hernial sac, the constricting band should be sought with the finger, and with this as a guide the point should be fully divided. In all cases the bowel was dark and ecchymotic, necessitating the exercise of good judgment in determining whether or not the vitality of the intestine had been impaired beyond repair. Careful search should also be made for any perforation. The intestine should not be returned to the abdomen until the surgeon had satisfied himself that no other point of constriction remained, and that the intestine was not gangrenous. If the condition of the patient permitted a prolongation of the operation, the radical cure of the hernia should be attempted. If the intestine was gangrenous, and the condition of the patient was very bad, an artificial anus should be established; if, however, the patient's strength was fair, it was better to make an end-to-end anastomosis.

Diagnosis of Strangulated Hernia.—Dr. Henry Roth opened the discussion by a consideration of this topic. He said that the interference with the blood supply accounted for the tension, irreducibility, pain, tenderness, dulness on percussion, and the absence of impulse on coughing. The cardinal symptoms were those of shock or collapse, and were very similar to those of any acute intra-abdominal disease or injury. The pain was referred to the hernia or to the umbilical region. It was colicky in nature, and was due to injury of the peritoneum, distention of the intestine, and active peristalsis. Vomiting was frequent, but afforded no relief, and soon gave rise to intense thirst. From the very onset there was complete constipation, as a result of reflex paralysis of the intestine. Indol, not being discharged from the intestinal canal, was changed into indican, and was found in the urine. The urine was diminished because of the low arterial pressure resulting from irritation of the abdominal plexus of nerves. The presence of tension and the absence of impulse were characteristic of strangulated hernia, and were not found in simple obstructed and irreducible or inflamed herniæ. An inflamed hernia was tender and painful, and presented the signs of a local inflammation. While there was a rise of temperature, as a rule there were little or no vomiting and none of the signs of collapse so obvious in strangulated hernia.

Treatment of Strangulated Hernia.—Dr. John F. Erdmann said that modern surgery had made the treatment of strangulated hernia at the present day a simple matter. He did not practise taxis for more than a few minutes, and not at all if it had been tried by others previously, or if a hard mass could be felt at the seat of obstruction. Half an hour before trying taxis he was accustomed to give a full dose of morphine, and to apply heat over the hernia. In his opinion, heat was more relaxing than cold. The surgeon should always obtain permission to operate at once if taxis failed. His experience had taught him to discard general anæsthesia, and rely entirely on the local anæsthesia produced by a one- or two-per-cent. solution of eucaine. Should the condition of the gut after relief of the strangulation be questionable, and the patient be not too feeble, hot towels should be applied to the bowel, and efforts made to restore the circulation for half an hour before deciding upon returning the bowel to the abdomen. An end-to-end anastomosis was preferable if the bowel was gangrenous, and the patient in fair condition. Whenever possible a radical cure should be performed.

Radical Cure in Operations for Strangulated Hernia.—Dr. Irving S. Haynes discussed this part of the subject. The sac, he said, should be carefully isolated from the spermatic cord. This should be easy if the sac was an acquired one; it would be more difficult if the hernia was congenital. Tearing a slit in the sac, even though it extended into the abdomen, need cause no apprehension, for it could be easily closed by suture. Having exposed the canal, traction should be made on the sac, the peritoneum around the ring loosened, and the sac ligated and cut away. He was opposed to retaining the sac because such a pad, instead of preventing recurrence of the hernia, would actually invite this very complication. The more closely the construction of the normal body could be imitated, the more lasting would be the result. All the veins but one or two should be removed with an excess of loose tissue. In children the internal ring was nearly behind the external ring. If a hernia was present the infantile condition would be found; therefore the inguinal canal must be reconstructed. The first step in this direction had been taken in the preliminary division of the internal oblique and transversalis muscles, and the transversalis fascia. The sutures should be applied from without inward behind the cord, about half an inch apart, and should be of chromicized catgut. The first suture was the most important; it should be placed close enough to the cord so that when tied the fibres of the fascia would hug the cord tightly, but not obstruct the circulation in it. Bassini's operation, in his opinion, was improved by constructing an internal ring. Silkworm gut and silver wire were the most objectionable materials, he thought, for sutures in these cases. Too much handling of the tissue, failure to remove masses of fat, and failure to check oozing were common causes of a poor result.

Femoral Hernia.—There were greater natural difficulties attendant upon operating on femoral hernia. Theoretically one had only to bring the inner end of Poupart's ligament down to the horizontal ramus of the pubic bone and fasten it there, but, no matter how skilfully this was done, there remained alongside the obliterated ring and canal large veins which could not be greatly compressed. This led to an inherent structural weakness. The sac should be separated from the surrounding parts, a ligature applied as high as possible, and the sac removed. Interrupted sutures of chromic gut, No. 2, should be used, and they should be applied from the vein inward.

Truss Management of Hernia.—Dr. William B. De Garmo took up this subject. He stated that the profession had unfortunately been very negligent regarding the prescribing and application of trusses. Patients who could wear light trusses, and whose herniæ never protruded under such support, were safe under such management; in those cases presenting occasional symptoms of strangulation, or when the patient was careless about keeping on the truss, operation was certainly indicated. He believed the operation for the radical cure should be done in almost every case of strangulated hernia. The post-operative treatment of such a case, in his practice, consisted simply in the use of a bandage for four or five weeks, and then dismissing the patient from observation. This showed his great confidence in the present method of operating for the radical cure of hernia. The author of the paper had very justly spoken against taxis; nevertheless, many would persist in employing it. In this connection he desired to say that, in performing taxis, instead of trying to put the hernia back, the effort of the surgeon should be to draw it further down. This did not imply the use of any violence, but if this little procedure was tried reduction would follow in many cases.

Age No Bar to Operation.—Dr. Charles N. Dowd opened the general discussion. He said that in glancing over the literature of this subject one could not fail to be impressed with the disastrous results attending delay in operating. This error was so common and so flagrant that it was a source of astonishment. Regarding the age of the patient, the speaker said that this was no bar to prompt operation. Recently he had seen a man, seventy-five years old, in a very feeble condition, and suffering from a strangulated hernia. When first seen there had been no constitutional disturbance, simply a painful and tender lump near Poupart's ligament. Exploratory incision was not permitted until the next morning, and then, on cutting down upon this mass under cocaine anæsthesia, a strangulated femoral hernia had been disclosed, and the constriction had been easily relieved. The operation for radical cure had then been done. This man, in his very feeble state, could not possibly have survived strangulation many hours. Dr. Dowd said that he had also operated easily and successfully for strangulated hernia on two infants, one four and the other six months old. These little ones had stood the operation just as well as adults.

The Operation Very Simple.—Physicians often hesitated to operate on a strangulated hernia, because they had a vivid recollection of the difficulties experienced as medical students in grasping the anatomy of hernia. This was unfortunate, for the operation was simple. The chief point to remember was to cut down to the aponeurosis of the external oblique muscle, and divide this tissue above the strangulation.

Dr. Lucius W. Hotchkiss indorsed what had been said by the last speaker regarding the comparative safety and simplicity of the operation if done at an early stage of the strangulation, and even at the extremes of life. He had himself operated for strangulated hernia upon a lady aged eighty-one years, and under full anæsthesia, with a perfectly satisfactory result. He had had equally good success in operating upon infants. There should be no delay in resorting to operation, except in those cases in which the diagnosis was in doubt, and in which, owing to the peculiar variety of the hernia, it was difficult to clear it up. When such uncertainty existed, it was well to remember that it was safer to operate than to wait and wonder.

Dr. Syms, in closing the discussion, said that while it was true that in a few exceptional cases taxis had succeeded, this result occurred so very rarely, and the usual consequences of taxis were so disastrous, that it seemed to him that the only safe rule was to discard taxis altogether.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 13, 1899.

W. H. Park, M.D., Vice-President, in the Chair.

A Case of Elephantiasis of Both Ears.—Dr. J. H. Larkin presented for Dr. Hodenpyl the specimens and photographs from a case of elephantiasis of the lobes of both ears, apparently produced by the irritation arising from the wearing of earrings. The removed portion measured 1.4 by 4 by 2 cm., and it had been taken from a lady aged thirty-seven years who was in good health. She stated that they had been enlarging for the past year and a half. Microscopical examination showed hyperplasia and a moderate exudate in the neighborhood of the blood-vessels. The speaker said that while elephantiasis of the lobes of the ears from wearing earrings was not unusual, the increase in size in this instance had been excessive.

Papilloma of the Larynx; Suffocation.—Dr. James Ewing presented the larynx taken from a woman, forty years of age, who had apparently been in good health until about ten days before death, when she had begun to suffer from very severe dyspnœa. She had been seen at the dispensary of Bellevue Hospital, and it had been noted that the obstruction to breathing was extreme. The woman had been admitted to the medical side of the hospital, but no definite diagnosis had been made. The peculiar character of the dyspnœa had led one of the house staff to suspect obstruction in the trachea. The laryngoscopic examination was negative, but had to be performed under difficulties. She had died in a few hours. The autopsy had shown the organs normal with the exception of an extensive chronic diffuse nephritis. On opening the larynx, just below the vocal cords was to be seen a gray and apparently necrotic mass, about 2 by 3 cm., attached by a small pedicle to the mucous membrane below the right ventricle posteriorly, and lying somewhat loose in the cavity of the larynx. It had caused an acute catarrhal inflammation in the upper half of the larynx and a necrotic inflammation of the mucosa immediately surrounding it. It almost completely obstructed the air passages, and fully explained the cause of death. It had been difficult at first to determine the nature of this body. It had been necrotic throughout, but on staining it in various ways remnants of an epithelial layer could be made out, and, in general, the outlines of a papilloma. The diagnosis, therefore, was papilloma of the subglottic mucosa; necrosis of this papilloma and suffocation. The speaker said that one or two laryngologists had seen this case before a microscopical examination had been made, and they had stated that papilloma of the larynx never caused death in this way. If this was true, the case must be looked upon as unique.

Tuberculous Ulcer at the Base of the Epiglottis.—Dr. Ewing also presented a larynx from a case of chronic miliary tuberculosis. It exhibited an ulceration of considerable extent at the base of the epiglottis. There were no gross lesions of the mucosa, but the entire base of the epiglottis was infiltrated with tuberculous tissue, and the base itself was the seat of an ulcer about 2 by 1 cm. Tubercle bacilli were found in this ulcer. This was a rather rare localization of tuberculosis of the upper air passages.

General Miliary Tuberculosis; Thrombosis of Superior Mesenteric Artery.—Dr. Ewing next exhibited specimens taken from a girl aged seventeen years, whose health had been failing for some months before her death. The chief symptom had been an irregular diarrhœa. About ten days before death this diarrhœa had been more severe, and had been associated with abdominal pain. The temperature had then risen, and the case had afterward followed the usual course of general miliary tuberculosis. At the autopsy the colon had been found to be the seat of a few rather old and not very extensive tuberculous ulcers, which were partly healed. There were also an acute catarrhal inflammation of the ileum and jejunum, and a considerable swelling of the lymphatic tissues throughout the lower ileum, but there were no tuberculous ulcers of the small intestine and no involvement of Peyer's patches. Beneath the stomach was a large mass partly adherent to the adjoining viscera. When dissected out it was found to consist of the mesentery in a state of extensive bloody-infiltration. There were thrombosis of the superior mesenteric artery, and suppurative arteritis with miliary tubercles surrounding the vessel, but not involving the clot. Besides the lesions of general miliary tuberculosis in this case, the lymph nodes at the root of the lung were very slightly involved; on the side of the neck were one or two which were slightly caseous. With the exception of the chain in the neck the chief seat of the lesions was the upper mesenteric region. The infection had probably arisen from the initial ulcers in the large intestine, and had lodged in these particular lymph nodes, and death had resulted from infection of the superior mesenteric artery, dissemination of the bacilli through this artery, and a complete general miliary tuberculosis.

Dr. Jonathan Wright said that if this growth of the larynx was simply a papilloma, the case was, so far as he knew, entirely unique. In tuberculous and syphilitic lesions there were apt to be papillomatous growths all over the mucous membrane of the larynx. Sometimes on removing these there would be left a deep ulcer beneath, and very frequently with syphilis there would be an involvement of the cartilage. He had seen these papillomatous masses in a case of tuberculosis of the larynx so marked that laryngectomy had been done and the inside of the larynx thoroughly scraped out, with the idea that the patient would recover with a sound larynx. Unfortunately the patient had died as a result of an accident. He would be very sceptical indeed as to a non-specific condition in the case just reported; it would be interesting to have sections made immediately around the ulceration and deeper down in the tissues with the object of searching for syphilitic lesions. The history pointed very strongly to syphilis of the larynx. Such patients often presented for a long time few, if any, symptoms until the onset of dyspnœa, which would then increase so rapidly that unless the treatment was prompt and effective the patient would be liable to die. A recent case was cited in which, although the dyspnœa had not been urgent, he had sent the patient to the hospital. The patient had, however, lost the note, and consequently there had been some delay. As a result, the man had nearly died before tracheotomy could be done. In that case there had been nothing but an abscess of the larynx of syphilitic origin. After having had an opportunity of examining macroscopically the specimen of papilloma of the larynx, Dr. Wright was ready to admit that he could discover no evidence of a syphilitic or tuberculous base to it. He had seen several cases of tuberculosis at the base of the epiglottis; while not very common they were not extremely rare. They were occasionally mistaken for syphilis, but the finding of the tubercle bacilli would easily settle that question.

Dr. W. H. Park asked if Dr. Ewing felt fairly confident that he could usually detect the primary lesion in cases of tuberculosis. He thought there might be cases of incipient pulmonary tuberculosis in which bacilli were swallowed, and thus intestinal lesions started, making it difficult to determine which lesions occurred first.

Dr. J. S. Thacher asked if there had been no further appearance of interference with the circulation of the intestine as a result of the cutting off of the superior mesenteric artery; under such circumstances there were usually very striking necrotic changes.

Dr. Ewing replied that whatever syphilis might have had to do with the first case of papilloma, he could not understand how a constitutional disease could produce a mass of this sort in the trachea. If syphilis was present it must have been entirely secondary as a cause of death. The anatomical condition was such as could hardly have been produced by syphilis. An interesting feature of the case was the absence of cyanosis and the presence of extreme pallor in spite of the marked obstruction in the trachea. Several cases which had been presented to this society seemed to emphasize this fact, namely, that slow asphyxia was apt to be associated with extreme pallor and not with cyanosis. It was, of course, impossible to say definitely which lesions had developed first, but in the case presented he thought it was highly probable that the intestinal tuberculosis had been primary. With regard to the condition of the intestine as a result of the thrombosis of this large vessel, he said that it was a matter for surprise that the changes had been so slight. There had been no areas of necrosis and no ulcerations, although the blood content of the intestinal wall was considerably increased. The thrombosis was complete, and partly organized.

A Case of Carcinoma of the Antrum of Highmore.—Dr. Leon T. Le Wald presented specimens from a man forty-five years of age. The condition had not been diagnosed before death; indeed, it was difficult to detect the presence of these tumors in the antrum of Highmore. The autopsy had disclosed a tumor obstructing the nasal fossæ, and growing apparently from the left antrum of Highmore into the nasal fossa on that side. From thence it had apparently extended upward through the sphenoid and ethmoid bones into the skull in the anterior fossa, and had produced a growth measuring about 2 by 1.5 cm. This had pressed on the left frontal lobe. The growth had also passed through the orbital plate of the frontal bone and back through the sphenoidal fissure into the middle fossa of the skull, producing a growth measuring 1 by 0.5 cm. This had pressed on the temporosphenoidal lobe of the brain. The tumor had also extended downward through the hard palate and had involved the mucous membrane of the mouth, and extending down the pharynx had involved the lymph nodes of the neck and even the bronchial lymph nodes. There were also growths in the lungs, apparently of a metastatic nature. Two nodules were also found in the upper surface of the liver. The primary growth appeared to have started from the left antrum, although there was some difference of opinion on this point. A number of sections of the tumor had been examined by Dr. Dunham, and had been found to be carcinoma.

Dr. E. K. Dunham said that the chief points of interest in this specimen were in connection with the lesions of the lung, where the neoplasm seemed to have appropriated the stroma of the lung tissue for its own purposes, and not to have developed any stroma in that organ. The microscopical examination had not been completed, but the specimen appeared to be one of medullary carcinoma of poor nutrition, there being large areas of necrosis. In the brain it had had certain peculiar anatomical relations with the blood-vessels. Sections of the growth were exhibited under the microscope.

Dr. Ira Van Gieson asked if the hypophysis or the optic tracts had been destroyed.

Dr. Le Wald replied that it had not involved either of these regions.

Dr. Jonathan Wright said that there were on record in laryngological literature two or three cases which had begun in the antrum of Highmore. One of these he had seen clinically and had examined microscopically. There had been some doubt regarding the nature of the growth. It was a polyp of the antrum which had gone down through the tooth socket and had appeared in the mouth. The patient had been between forty-five and fifty years of age. The growth having been thought to be simply a polyp, an operation had been undertaken, but it had been found that the antrum was filled with grumous material. The tumor had been about the size of a black walnut, perfectly round, and having a rather large pedicle. It had evidently filled the whole antrum. Thick sections had been made through the whole polyp from one side to the other, and deep down on the stroma it had presented a perfect picture of epithelioma. Dr. Prudden had confirmed this diagnosis of epithelioma. The case had been followed for over a year, and there had been no recurrence. This, and one other case in literature, were the only ones he knew of in which it had been definitely stated that the growth had originated in the antrum of Highmore. It was quite possible that more cases were on record, as most of them came under the observation and care of the general surgeons.

A Case of Congenital Atresia of the Duodenum.—Dr. J. S. Thacher presented a specimen in which the small intestine appeared to be the continuation of the common bile duct. It had been taken from a child who had died at the age of six days, having been operated upon two days before for an imperforate anus. The child had vomited all food. No communication could be found between the duodenum and the stomach.

Extreme Stricture of the Urethra with Secondary Cystitis and Hydronephrosis.—Dr. Thacher also presented specimens from a case in which the immediate cause of death had been poisoning by carbolic acid taken with suicidal intent. The autopsy had, however, revealed extensive disease of the genito-urinary tract, and particularly a very narrow stricture of the urethra. An opening about the size of the shaft of a pin had been found after some searching, in the centre of an oblique membrane which had occluded the urethra. There had been no clinical history, but it had been assumed that the membrane was of a cicatricial nature.

Dr. Moschcowitz remarked that it was certainly not such a stricture as would arise from traumatism or from gonorrhœa, and consequently he would like to know more regarding its nature. Might not this stricture be congenital?

Dr. Thacher said that he had, perhaps hastily, assumed the stricture to be the result of inflammation, or possibly of inflammation aided by trauma.

Double Spleen.—Dr. Lewis A. Conner reported a case of double spleen and exhibited the specimens. Each spleen measured approximately 8 by 5 by 2.5 cm., and weighed 60 grams, and each had its own branch of the splenic artery, and was, in other respects, apparently normal. Of course, a small supernumerary spleen was very frequently met with, but he had never before seen two spleens of the same size.

A Case of Perforating Duodenal Ulcer.—Dr. Conner also presented a duodenal ulcer removed at an autopsy made a few hours previously. The patient had entered the Hudson Street Hospital with symptoms closely resembling those of appendicitis. Dr. Bolton had made the usual incision for appendicitis, and had found the right side of the abdomen filled with a thin, purulent secretion, and the appendix normal. Through a second incision the pus had been seen to come from the region of the liver and diaphragm. There had been no evidence of gas in the peritoneum at the time of operation. The man had lived for nearly a week after operation. The autopsy showed a severe peritonitis localized around the cæcum and along the ascending colon, but there was no general peritoneal infection. An old oblong ulcer was found immediately below the pylorus, which had had the peritoneal coat for its base for some time, and which had finally perforated by a minute opening. Near this was what appeared to be the scar of another ulcer. There was a history of a similar attack four years ago. Surgeons were beginning to realize that, in general, the higher up the perforation the milder the infection and the better the prognosis, and the case just reported seemed to bear out this view. In this case there had also been a croupous inflammation of the cæcum and ascending colon—in other words, that part of the intestine adjacent to the infected area of peritoneum.

Dr. Park said that this idea about the mildness of the inflammation in cases of high perforation was new to him and most interesting. In the duodenum there were usually but few bacteria, and those largely from the food, which had escaped the deleterious action of the gastric juice while in the stomach.

Dr. Harlow Brooks said that at the last meeting he had presented three cases of duodenal ulcer, and was therefore particularly pleased to observe the close similarity between this case and his own. The presence of a non-odorous pus, and of symptoms of appendicitis, made the similarity very close, and emphasized again the importance of the character of the abdominal exudate as indicating the presence of duodenal ulcer.

Dr. Conner said that he had been informed that interesting bacteriological investigations had recently been made by Dr. Cushing at the Johns Hopkins Hospital regarding the intestinal tract, and these had suggested the line of thought just presented.

Dr. Theodore Janeway asked if perforating ulcer of the stomach did not often produce gas abscess underneath the diaphragm, with the production of very foul pus. He had seen such a case last year, in which the first symptom of ulcer of the stomach had been perforation. The woman had gone into collapse and had developed a gas abscess. This had been operated upon in four days, and she had lived a week subsequently. The autopsy had shown a very general peritonitis, but more especially localized in the region of the diaphragm, liver, and stomach. The pus had had a very foul odor, and the gas had formed rapidly even after aspiration. In another case which he recalled there had been associated with severe pain in the upper part of the abdomen, and collapse, the development of friction sounds over the spleen and evidence of a slow abscess formation. After about one hundred days the abscess had burst into the left pleural cavity, and the pus had been found to contain only streptococci. About forty days later, when apparently doing well, the patient had died with symptoms of secondary abscess of the brain.

Dr. E. Libman mentioned a case of perforation of a gastric ulcer associated with thrombosis of the upper branch of the splenic vein. There were infarction and gangrene of the upper half of the spleen, with very foul pus and gas in the subphrenic space. Cultures showed streptocococci and the bacillus proteus vulgaris. With reference to the greater virulence of perforations in the lower part of the intestine, he referred to an investigation made by him some years ago on streptococcus infections of the bowel, as a result of which he had found that the streptococci increased in number from the duodenum down, and had been most numerous in the cæcum and lower part of the ileum, and that the changes had been most marked in the latter regions. This was possibly due to greater stagnation in these places.

Carcinoma of the Liver Secondary to Small Mammary Cancer.—Dr. George P. Biggs presented a specimen taken from a woman, sixty-five years of age. No history of the case could be obtained. The liver was found at autopsy to be greatly enlarged and to contain an enormous amount of carcinomatous tissue (chiefly in the form of nodular masses 1 to 3 cm. in diameter). A careful search through the abdomen and thorax failed to show any other carcinoma. Finally an examination was made of the breasts, both of which were quite small and of equal size. There was nothing in their outward appearance to suggest the presence of a tumor, but on palpation the right breast was found to be very firm, and incision revealed a scirrhus carcinoma involving the whole mammary gland which measured but 6 by 5 by 15 cm. Metastatic deposits were found in the right axillary glands. Microscopical examination showed a marked similarity in the type of cells found in the tumor tissue from the breast and the liver, and suggested the probability that the involvement of the liver was secondary to that of the breast. Additional evidence in support of this conclusion was to be found in the fact that it was the right breast which was involved, and that from this tumor metastasis had occurred in the axillary glands. It was of course possible that there might have been independent development of tumor tissue in each organ, but this seemed improbable. The case served to emphasize the importance of great thoroughness in making post-mortem examinations.

Dr. Van Gieson raised the query as to why the tumor in the liver should have grown to such an enormous extent while the carcinoma of the mammary gland had apparently ceased growing.

Dr. Biggs replied that he had no explanation to offer. There did not appear in the sections to be any association of the growth with the bile ducts.

Dr. Ewing commented upon the gross appearance of this liver. He asked if there had been any distinct indications of secondary growth, or if it had been uniformly distributed as in the section exhibited.

Dr. Biggs replied that it had been uniformly distributed.

A Case of Foreign Body in the Appendix Simulating Gall Stone.—Dr. J. H. Larkin presented a specimen removed from a man, fifty-four years of age, who had given a clinical history of repeated attacks of gall-stone colic for a number of years. About three days before admission to hospital there had been an unusually severe attack of pain, accompanied by fever and depression. He had been in the hospital only an hour or two when the symptoms had become very urgent, and the man had died before he could be operated upon. At the autopsy forty-one gall stones had been found in the gall bladder, and in the intestine three stones. The common duct had been greatly dilated, and there had been evidence that a number of large stones had passed through the duct at different times. The vermiform appendix was found twisted upon itself, and turned upward and backward. The middle portion was free, but the tip was adherent to the cæcum and could not be separated. The appendix being opened, it was found that its tip had perforated into the cæcum, and projecting through this opening was a stellate-shaped stone. On slitting up the appendix further he had found three stones—one in the shape of a clover-leaf and the other two with facets, one having six and the other four. Chemical examination of these stones from the appendix showed them to be simply enteroliths and not gall stones. They differed from ordinary enteroliths in their shape and in the presence of facets. The lumen of the appendix had been entirely obliterated, and microscopical examination had revealed a complete replacement fibrosis of the lumen, there being no remains of epithelial or glandular tissue. Mitchell had made a rather recent contribution to this subject, and had collected fourteen hundred cases of foreign bodies in the appendix. Out of this large number, cases of gall stones in the appendix had been reported by only three observers.

Dr. Conner thought it not impossible that these stones from the appendix were really gall stones, and the fact that one of them presented six facets seemed to point very strongly to this stone having been associated with a number of other stones. He suggested that such stones might lose some of their chemical characteristics after having been for some time in the bowel.

Dr. Larkin replied that in the chemical reactions of the enteroliths in the appendix cholesterin had not been found. The appendix itself showed that a chronic process had been going on for a long time. The chemical examination had shown very definitely that these stones in the appendix were not gall stones. The three stones present in the appendix might have produced a large number of facets. The formation of these facets seemed to him to be the result of muscular action.

Dr. Theodore Janeway asked if the chemical examination had been made from the exterior, or whether it had been made on the interior, or by section.

Dr. Larkin said that quite a large piece of one of the stones had been chipped off and subjected to chemical examination.

Colonies of the Plague Bacillus.—Dr. W. H. Park exhibited agar culture and stained preparations from agar and bouillon cultures of the plague bacillus obtained from the cases of bubonic plague found on the steamer *J. W. Taylor*. He said that although full half a cubic centimetre of pus had been extracted from the buboes of the ship's captain and cook, only three to five colonies had developed in each case. The rapid disappearance of the bacilli at the time of the pus formation in the buboes had been noted by the earlier observers. Their form, cultural and staining characteristics were identical with those of two cultures obtained from that disease which had been brought to him from India.

Mucinæmia and its Rôle in Experimental Thyroprivia.—Dr. Isaac Levin read a paper with this title (see page 184).

The Chemical Relationship between Mucoid, Colloid, and Amyloid Substances in Normal and Pathological Tissues.—Dr. P. A. Levene read this paper (see page 188).

Dr. James Ewing asked what had been the result of the examination of the blood in cases of thyroprivia as regards the presence of mucin.

Dr. I. Levin replied that it was exceedingly difficult to detect such small quantities of mucin.

Dr. Van Gieson said that these papers, and particularly the second one, were interesting as showing what it was possible for the physiological chemist to do in the way of aiding the pathologist. One more link would be added to the proof of the presence of mucin in the system. If the animals deprived of thyroid, after having been injected with mucin, had been supplied with artificial thyroid extract it should have, theoretically at least, prolonged their lives.

Dr. I. Levin replied that the trouble in experimenting in this way with the thyroid extract was, that this extract was of a most uncertain nature. The advantage of working with mucin was that one knew the nature of the substance with which one was working.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, January 25, 1900.

Brooks H. Wells, M.D., Chairman.

Removal of Fibroids through an Anterior Vaginal Incision.—Dr. J. Riddle Goffe reported a case of a woman, forty-three years of age, married twenty-three years and the mother of two children. Examination had revealed a small fibroid in the posterior wall of the uterus, just above the internal os. He had operated for the removal of this tumor through an incision in the anterior fornix of the vagina. Having delivered the uterus into the vagina, the tumor had been very accessible, and had been easily shelled out through a longitudinal incision. He had then shortened the round ligaments through the same incision. The woman had made an uninterrupted recovery, and had left the hospital in three weeks.

Dr. Goffe also exhibited six fibroids removed from another woman, forty-three years of age. The tumors had been removed through the anterior incision by myomectomy. The woman had come to him complaining of backache and hemorrhage. He had previously curetted and packed the uterus, and this had proved a useful means of support during the subsequent insertion of the sutures into the uterus. In this case he had shortened the round ligaments and sutured the perineum. The patient had left the hospital on the twentieth day.

Dr. A. Brothers said that about eighteen months ago he had presented to the New York Obstetrical Society a number of fibroids, of about the same size as those just shown, and had been severely criticised for having removed such small tumors, the statement being made that such tumors never gave rise to symptoms of any importance. It was therefore reassuring to know that a surgeon of Dr. Goffe's reputation should see fit to do this operation. He would say incidentally that the patient from whom he had removed these fibroids had been restored to complete health, and instead of being an invalid she was now able to earn a living by laborious work.

Hysterectomy by the Clamp Method.—Dr. A. Brothers presented three uteri removed by the clamp method. The first case was that of a woman who had had many attacks of pelvic peritonitis during the previous twenty years, and who was anxious to have a most radical operation done. The uterus had been removed by the anterior median incision. The operation selected was vaginal hysterectomy by the clamp method, no effort being made at hæmostasis until the fundus of the uterus had been delivered through the vaginal incision. In the second case also he had begun by slitting up the anterior uterine wall, but had found it necessary subsequently to bisect the uterus. It had then been possible to reach the tumor and shell it out. The third specimen was a uterus which had been removed in one mass. The woman had suffered from frequent and severe uterine hemorrhages. Another gynæcologist had previously attempted to relieve this patient by curettage and amputation of the cervix, but without benefit. Dr. Brothers said that he had tried intra-uterine vaporization, having been hitherto very successful in stopping hemorrhages in such cases by that method. For the first time this had also failed him, and he had then removed the uterus, suspecting the presence of malignant disease. In this case the uterus had been simply drawn down and clamped in three different portions from below upward. On one side the adnexa had been completely removed. A different technique had been employed in this case because of the suspicion of malignancy.

Dr. P. A. Harris said that increasing experience showed that quite a large percentage of cases of myoma and fibroma ultimately proved to be malignant. This brought up the subject of the advisability of removing small tumors for slight symptoms occurring rather late in life.

Interesting Complication following Cervical Dilatation for the Cure of Sterility.—Dr. A. Ernest Gallant reported this case. The patient, a woman of thirty-one years, had been married ten months. He had first seen her last March, and as she had been very desirous of becoming pregnant, he had corrected a retroverted uterus and dilated the cervix. This was on March 18th, and she had menstruated on March 31st and on April 26th, but missed her menstrual period in May. Shortly after this she had an attack of pelvic peritonitis. On July 13th he had found a mass to the left of the uterus, and the organ was down on the pelvic floor and pushed to the right. The breasts were enlarged as in early pregnancy. He had made a diagnosis of extra-uterine pregnancy, and this diagnosis had been confirmed by Dr. Grandin. The following day he had performed abdominal section, and had found the omentum adherent to the tumor, and blood clots scattered through the intestinal coils. The fœtal sac had been found and removed. It was an unruptured tubal pregnancy as proved by microscopical examination. In the specimen no trace of tubal structure could be detected. It was thought to be a seven weeks' gestation. The hemorrhage had apparently occurred so late from a small opening found below the sac. The woman had insisted that one tube and ovary should be left if possible, and the right tube and ovary had accordingly been allowed to remain, although a cheesy mass had been found in that tube. Just beyond this mass the tube was bent at a right angle. When seen again on September 28th a pelvic examination had shown the uterus to be in good position. On September 4th she had menstruated scantily, and on October 2d she had flowed freely. In November and December the flow had been scanty, and she had returned to him for examination in December because of an uncomfortable feeling in the pelvis. A mass was found on the right side. Two days later, while at the theatre, she had fainted and had had to be taken home. A pelvic exudate had been found, but this had disappeared within a week under the use of hot douches. A second examination then showed a large mass on the right side extending up to the umbilicus. On January 15th he had operated upon her again, and had found several thin-walled cysts which had separated the broad ligament down to the cervix on the right side. A portion of the tube was allowed to remain. Microscopical examination of this specimen showed, to his surprise, a beginning alveolar sarcoma of the right ovary.

Dr. Goffe said that he was inclined to think that the restoration of the uterus to its normal position had been quite as important a factor as the dilatation of the cervix in causing pregnancy; however, the promptness with which pregnancy had ensued was certainly unusual. The malignant disease had developed so rapidly that it was rather difficult to believe that no indication of it had been present at the time of the operation for the extra-uterine pregnancy.

Dr. Brothers said that some years ago he had succeeded in relieving an obstinate metrorrhagia by means of curettage. The woman had returned after her marriage, and he had treated her then by negative galvanization because of a return of the metrorrhagia. Subsequently she had come to him with symptoms indicating that an extra-uterine pregnancy had ruptured while she had been on her way to his office. The diagnosis had been confirmed by Dr. A. J. C. Skene. Dr. Brothers had operated upon her forty-eight hours later, and had removed a ruptured ectopic gestation. He felt that the galvanization had acted as had the cervical dilatation in Dr. Gallant's case, and it was probable that in both instances some tubal disease had existed prior to the treatment.

Tuberculosis Complicating Pregnancy.—Dr. Hubbard W. Mitchell reported two cases of women who had had pulmonary tuberculosis complicating pregnancy. The first patient had consulted him in 1894 for advanced pulmonary tuberculosis. She was then about eight months pregnant, and her condition was so serious that it had seemed doubtful if she would live to the end of her pregnancy. She also had an extensive laceration of the cervix and perineum. On April 30th she had been speedily delivered at full term without any medical attendance of a well-formed child. Two other children had been born to her since then, and she was now in good health. Numerous examinations of the sputum had failed to show any tubercle bacilli. The second case was almost a counterpart of the first one, except that numerous tubercle bacilli had been found in the sputum. The good results of the treatment of the tuberculosis in these cases the speaker attributed to the use of an antiseptic tonic internally.

Dr. Goffe remarked that it had been frequently noticed that women in advanced stages of consumption were very apt to become pregnant—indeed, the same was true when the husband was tuberculous.

An Ovarian Cyst with Twisted Pedicle Mistaken for Appendicitis.—Dr. Brooks H. Wells reported a case showing certain difficulties in diagnosis. He had been called recently to see a woman supposed to be suffering from an attack of acute appendicitis. Up to a few days before she had been in perfect health. Constipation was marked, and a few hours before his arrival she had gone into collapse. The abdomen was enormously distended and extremely tender, so that palpation was out of the question. She was operated upon in the middle of the night, so great had been the urgency. An incision had been made over the region of the intestine. This had revealed a beginning general peritonitis, and also had disclosed the fact that the appendix was adherent to a mass about the size of an orange situated below the brim of the pelvis. The appendix itself was not inflamed. After making a median incision he had found a small ovarian cyst with two complete turns in its pedicle. The abdominal cavity had been flushed out and closed with a quantity of hot saline solution remaining in it. The woman had made a rapid recovery.

Dr. P. A. Harris recalled one similar case, except that the tumor had been sufficiently large to be detected by palpation before operation. She had had three attacks of severe pain, and, as a result of the twisting of the pedicle, a hæmatocele had been produced.

Pyloric Obstruction.—In nineteen cases with recovery and without relapse, Morison, of London, has operated by making an incision one and one-quarter inches from the pylorus, passing a guide through this opening and incising through all the coats. Suturing the incision is done in such a way that the line of union is transverse to the incision.

Medical Items.

New Jersey's Birth and Death Rate.—According to the State board of health report issued on November 29th, there appears to be a decrease of about five thousand births below last year's returns. The number of deaths for the year was 30,999, and the estimated population is 1,855,872, showing a death rate of 16.7. During the year there were 10,357 deaths of children under five years, and 8,042 deaths of persons over sixty years old. The victims of consumption numbered 3,584, and of acute lung trouble 4,322. The number of deaths from consumption was 419 greater than the average number for the previous twenty-one years.

Bravery of a Surgeon in South Africa.—Surgeon-Captain R. A. Buntine, who is mentioned in despatches for conspicuous bravery in the action at Bester's near Van Reenen's pass, is an Australian born in Melbourne. He was educated at the Scotch college in his native city and then at the University of Melbourne, where he took his degree as a physician. Dr. Buntine is in practice in Pietermaritzburg, the Natal seat of government. When the colonial volunteers were called out, Dr. Buntine and his partner, Dr. Currie, at once set off. The Carabineers were given the duty of patrolling the Free State border, and Dr. Buntine was out with them when they had a brush with the Boers at Bester's just under the Drakensburg, towering ten thousand feet above them. The Carabineers were compelled to retire, and a trooper who was wounded had to be left where he fell; Dr. Buntine, however, rode back for him and got his trooper servant, Duke, to accompany him. Dr. Buntine placed the severely wounded trooper on his own horse and held on to the stirrup leather of his servant's horse, and so ran back to camp.—*Lloyd's News.*

Fees in the United States.—The *West London Medical Journal* says: "Some attention was recently directed in an American medical journal to the professional fees paid to 'physicians' in the States, and the curious fact was pointed out that a fee of $500 was quite exceptionally netted. In the land where millionaires abound as well as men of large wealth, this certainly seems a surprising thing. A surgeon not long ago operated successfully for appendicitis in San Francisco, and his millionaire patient voluntarily handed him a draft for $30,000. This fee must eclipse any record we have in this country. If anything, however, there are signs everywhere that 'operation stock' is a falling market. That is to say, the fees for operations are not what they used to be. Many causes no doubt are contributing to this doleful state of affairs, but perhaps the most active of all is the increasing number of those in whose hands the public find that their surgical needs can be placed. Thus by competition combined with efficiency the operation stock market is being depressed."

Mr. Frederic Treves.—Few men who have gone to the front to care for the wounded at their country's call have more to lose and less to gain by so doing than Mr. Frederic Treves. Still a comparatively young man, his professional career of barely twenty-five years has been one continuous succession of scientific triumphs, and what is peculiarly gratifying to the profession in both his self-sacrificing offer and the high appreciation accorded to it by the government is that Mr. Treves' bright position is based solely upon purely scientific attainments and operative skill. He is emphatically a surgeon's surgeon and owes nothing of his reputation to medical politics or attendance upon distinguished personalities or households. The range of his work has been remarkably wide. Beginning as an anatomist or "dissector," his first marked success was a work which is to-day a standard text-book in every dissecting-room in which the English language is spoken. Then he turned his attention to the structure of some of our animal cousins, and his "Anatomy of the Intestinal Canal in the Mammalia" is already a classic, while the growth of his latest phase of reputation, the surgical, may be seen in his great "System of Surgery," published two years ago, and in the fact that within the past year he has been compelled to resign his chair at the London Hospital on account of the pressure of his private practice. And the personality of the man is worthy of his reputation—a commanding presence, a brilliant lecturer, with a remarkable gift of keen, incisive epigram, each sentence short, clear cut, and decisive, but with illuminating bursts of sunniest humor, he is the idol alike of his students and patients. His bearing in the operating-theatre is that of a general upon the field of battle.—*Outlook.*

Marvellous Draught of Fishes, Nine at a Birth.—It was reported by *The Lancet* correspondent at Rome that a marvellous story came from Casteldaccia near Palermo, and which was actually credited by the simple-minded Italian peasantry. The story ran that a woman at the above-mentioned place was, after a laborious confinement, delivered of nine little animals in the form of fishes, four of which weighed 15 grams apiece, and five 10 grams each. It is satisfactory that the latest news gave the mother as progressing as favorably as could be expected under the exceptional circumstances. *The Lancet*, commenting on this Munchausen-like tale, says: "Nihil sub sole novum." The Palermitian monstrosity, which has been going the rounds of the Italian press lay and professional, has evoked references to other lusus naturæ, of which Italy appears to have been from time immemorial the chosen seat. The painstaking and matter-of-fact historian of imperial Rome, from the death of Marcus Aurelius—Herodian to wit—has been laid under contribution, and his statement of the portents that marked the close of the reign of Commodus has had the honor of resuscitation: *ζῶα τε παντοῖα καὶ τὴν ἑαυτῶν φυσὶν μὴ τηροῦντα σχήμασι τε ἀλλοδαποῖς καὶ μέρεσι σώματος ἀναρμόστοις πολλάκις ἀπεκυήθη* (animals of all kinds deviating from their natural constitution were frequently brought to birth in strange forms and with parts of their body out of all harmony with each other). The time is ripe for a new edition of Geoffrey St. Hilaire's classic work on tetratology, were it only to utilize the material bearing on the subject, and chiefly to be found in the anatomico-pathological museums of the Italian medical schools.

A Preliminary Note on the Experimental Introduction of Cancer.—For some years the author has held the view that carcinoma is simply the result of the entrance of the normal epithelium of the body into the lymphatic spaces and its continued growth therein; his reasons being that the epithelium of cancer is practically identical with the normal epithelium of the body, that the spread of cancer always takes place along the lymphatics in the direction of the lymph flow, and that carcinoma is infectious. The epithelial cells themselves are in all probability the infective agent. In order to put this view to test the following experiment was made: The ovaries in a rabbit were incised, the cut surfaces scraped, and the juice containing free epithelial cells thus obtained was allowed to enter the peritoneal cavity. The animal remained well for nearly a year, then became thinner and weaker and dyspnœic, and was killed. On examination numerous white, hard nodules, varying in size from a pin's head to an olive, were found in the mesentery, liver, uterus, diaphragm, parietal pleura, lungs, and mediastinum. In structure these nodules had all the characters of ovarian cancer, consisting of alveolar spaces lined by one or occasionally more layers of columnar epithelial cells.—*Journal of Pathology and Bacteriology.*

Increase of Cancer in Great Britain.—The assertion that the increase in the deaths from cancer in Great Britain is more apparent than real, owing to a variety of causes, has been advanced frequently of late by those who distrust statistics. This may be and probably is the case to a certain extent, but to contend that cancer has exhibited no increase is wilfully to ignore incontrovertible facts. *The Lancet*, referring to the matter, has this to say: "Perfectly accurate figures show that the registered mortality from malignant disease in England and Wales has at least doubled within the last fifty years. Among males, indeed, there has been an uninterrupted increase from 19.5 per million of the male population to 571 per million in the later years of the last century." No verbal juggling or explanations can do away with the significance of these figures, and the quibblers must allow that, while admitting that an exaggerated view is taken of the greater prevalence of cancer by some. The truth is plain that there has been a very considerable increase of malignant disease both in this country and Great Britain.

Gunshot Wound of the Brain Through the Mouth.—Barker (*Lancet*, December 2, 1899, p. 1508) reports the case of a man, twenty-nine years old, who discharged two shots from a small-bore revolver into his mouth in a direction upward and backward. There was at first free bleeding from the nose, and this was plugged. On the following day the man was able to sit up in bed, bleeding moderately from the right nostril; he was perfectly conscious and quite intelligent, and complained only of a slight general pain in the head over the right side. The pupils were normal, and the only paralytic symptom was a slight droop of the right eyelid, which was also slightly ecchymosed. There was a round hole in the hard palate, just to the right of the middle line, two inches from the edges of the incisor teeth, and this was still bleeding. The plugging was removed, the wound dusted with iodoform, the patient kept at rest, and ice applied to the head. Vomiting occurred a few days later, and was repeated again after the lapse of two weeks. Ten days after this weakness appeared in the left arm and leg; the lines on the left side of the face were thought to be a little less marked than on the right, and the tongue deviated a little to the left. The pupils were still equal, though small, and they reacted to light. Intense optic neuritis with hemorrhages was found in the right eye, and also in the left though in less degree. The knee-jerks were increased on both sides, and ankle-clonus was present on the left. There was slight tenderness on percussion over the right parietal bone. The urine was normal, and the intellect perfectly clear. Vomiting without nausea recurred from time to time. The temperature was but little above normal. At no time did twitchings or convulsions occur, though carefully looked for. For a period there was steady improvement in all of the symptoms, so that it was deemed unwise to attempt removal of the bullets in the skull. Skiagrams showed that one of these lay near the body of the sphenoid bone outside the brain, and the other exactly in the middle of the brain. On careful measurement from the glabella to the external occipital protuberance the latter bullet was found directly under a point midway between the two, and at a depth of about one and three-quarters inches from the surface of the skull. Allowing for the difference in size between the patient's cranium and its shadow, it was thought that the bullet ought to have rested on the corpus callosum at about two-fifths the distance from its anterior extremity, and against the lower border of the falx cerebri, one-eighth of an inch to the right of the median line. On the sixth day after the injury the patient had a convulsion lasting from three to five minutes with loss of consciousness, but without localizing symptoms. The attack was preceded by a feeling of chilliness, then by a rigor, and the temperature was found to be 100.6° F. Two days later two additional attacks occurred, and the day after this a fourth. Operation was now decided upon, and after some difficulty the bullet was removed. On restoration of consciousness sensation and motion were absent at first upon the entire left side, except in the face. Improvement, however, in these symptoms took place, although clonic contraction at the elbow occurred from time to time, and also in the left calf. The knee-jerk was exaggerated upon the left, and ankle clonus was present. In the later history of the case secondary trephining was practised, with separation of some adhesions between the hemispheres. This was followed by a large number of epileptic attacks within a few days, but subsequently the patient improved.

Premature Maturity of the Japanese.—By examining statistics for the past five years, the *Jiji Shimpo* finds that the average age of students graduating from the Imperial University is twenty-six years and one month. The discovery causes that paper much disquiet. It says that young men in Europe graduate at twenty-two or twenty-three. On the other hand, the Japanese mature at an earlier age than Europeans do, and their lives of robust activity are shorter. In Western Europe a man is considered to be in his prime at fifty, and at sixty and even seventy he occupies the most important posts and discharges the most arduous duties. In Japan, on the contrary, a man is thought to have lost his capacity for usefulness at fifty, and is expected to step aside and make way for his juniors. So it would seem that there is a difference of ten years in the length of active life, and a difference of about five years in the time of concluding the scholastic career, the total loss on the Japanese side being fifteen years. Such figures naturally alarm our contemporary, and it appears to think that the only feasible plan is to reduce the standard of education. Beyond all doubt some means should be taken to enable youths to finish their university course at an earlier age. If twenty-six years is the average age of graduation, there must be many men of thirty studying in the university. But is it quite correct to say that active life is over in Japan at fifty? A large number of the leading merchants and statesmen of the present day are nearer sixty than fifty.

Cotton-Seed Oil as Food.—In an editorial under the above title *The Lancet* (July 29, 1899) says that because cotton-seed oil has been employed as an adulterant a certain amount of prejudice is entertained against its use as a dietetic. The ease with which it saponifies would indicate that this oil is a useful food and an excellent substitute for more familiar fats; in fact, properly refined cotton-seed oil is as wholesome as butter. The late Dr. Campbell Morfil devoted considerable attention to this subject, and concluded that the daily consumption of a small quantity of cotton-seed oil produced results unattainable from any other food, in cases of chronic dyspepsia, in which the diet was restricted and the stomach intolerant of other fat. It is less nauseating than cod-liver oil and free from its laxative tendencies, and may therefore be exhibited in tuberculous patients in whom excessive waste has to be combated without overtaxing the digestive functions. When properly refined the oil has a sweet, nutty flavor, and does not tend to become rancid. It is well adapted for culinary and edible purposes, but should not masquerade under a *nom de plume*.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended February 9, 1900:

		Cases.	Deaths.
SMALLPOX—UNITED STATES.

Japanese Barbers and Infectious Skin Diseases.—The Tokyo police have summoned all the barbers of the capital and conveyed to them strict instructions with regard to cleanliness and the use of disinfectants, as well as the duty of not shaving persons that are suffering from skin diseases or other maladies of a contagious nature. The chief of police has also instructed the constables serving in the city to observe the conduct of jinrikisha-men, and to interfere at once if they detect any attempt to importune citizens, or to behave rudely toward persons who refuse to employ jinrikisha.

ON THE TREATMENT OF THE SLIDING HERNIAS OF THE CÆCUM AND SIGMOID FLEXURE.[1]

By ROBERT F. WEIR, M.D.,
NEW YORK,
PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS; PRESIDENT OF THE AMERICAN SURGICAL ASSOCIATION, ETC.

THE natural looseness of the peritoneum in the iliac regions of the abdomen allows not very infrequently the slipping or sliding of portions of the large bowel into a hernia, and thus makes a decided variation in the ordinary contents of a hernial sac. For instead of this sac being formed by the pushed-out parietal layer of the peritoneum, in which rests, ordinarily, free or adherent omentum, small or large intestine, in these slipped hernias, the "hernies par glissement" of the French authors, there is found an important variation in these usual conditions. It is, that the proper peritoneal sac is imperfect, usually on its postero-lateral aspect, where, instead of passing around the included bowel, the loose peritoneum rises up and passes over the herniated bowel to its other side. In other words, the protruded bowel is still outside the peritoneum. Figs. 1 and 2 show this more clearly than words can do. In these it will be seen that the bowel has been forced down, carrying with it a fold of loosened peritoneum into the scrotum, just as is done in the descent of the testicle. And, indeed, the congenital form of cæcal hernia is produced by the same agent that helps the descent of the testis, for the gubernaculum testis is included in the duplication of the peritoneum that contains the cæcum, and hence the bowel, from its action, is occasionally drawn down in the wake of the testis. A similar occurrence, although more rarely than with the cæcum, may happen on the left side where the gubernaculum ends under the sigmoid flexure.

Not every case, however, of cæcal or sigmoid hernia is of this kind; on the contrary, most of the cæcal variety and many of the sigmoid ruptures are found to have complete sacs owing to the fact that they are generally covered all around by peritoneum in their normal condition. This is particularly true concerning the cæcum and appendix, and it is a point of supreme surgical interest in connection with the surgical lesions of the latter, for which we are largely indebted to Treves for having made it widely known to us, although Scarpa, as long ago as in 1812, and later Bardeleben, in 1849, and other German observers early proclaimed the fact and its value in connection with perityphlitis. This mobility of the cæcum with its perfect peritoneal covering, which is only wanting in about eighteen per cent. of the observed cases, and a nearly similar condition in the sigmoid, where it is limited only by a mesocolon, narrow and of varying length, will explain why so many cases of cæcal and sigmoid hernias have been treated radically without surgical difficulty and with success. Such conditions are not considered here. Moreover, when the colon retains its long mesentery, which is its original development, the cæcum can present itself in a left-sided hernia or, vice versa, the sigmoid can show itself in a rupture on the right side of the body. *En passant*, this arrest of development from a long to a short mesocolon additionally permits the understanding of the left-side appendical difficulties which are occasionally encountered, and does away with the need of calling in the transposition of the viscera to help us in such questions. Macready says, concerning the variations of hernias of the cæcum, that in fifty-seven instances thirty-six were right inguinal; five were right femoral; nine were left inguinal, and one was left femoral.

Most of the cæcal and sigmoid hernias are reducible, which means that they generally have a complete sac and that the intestine rests free as it does in other hernias. Merigot de Treigney[1] collected an interesting number of cases of hernias of the large intestine and presented them as follows:

	Inguinal.	Crural.	Total.
Cæcum and appendix	8	5	13
Cæcum and end of ileum	11	..	11
Appendix alone	17	5	22
Transverse colon	4	..	4
Totals	40	10	50

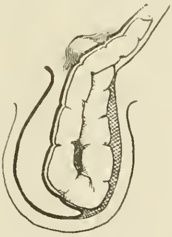

FIG. 1.—Showing the Large Intestine behind the Peritoneum.

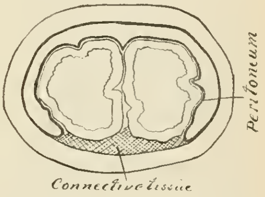

FIG. 2.—Showing the Retroperitoneal Large Intestine in a cross section of the hernia with its incomplete sac.

With such hernial contents this class of ruptures can, as a rule, be readily reduced.

A brief digression may be here made to express clearly the distinction which should be, but is not generally, made between a cæcal hernia and one of the ascending colon and on the left side, between a sigmoid hernia and hernia of the descending colon. In reality it is anatomically well known, and it has been already alluded to, that the cæcum should be considered with a few exceptions as entirely surrounded by peritoneum; it is, however, not so well known that the sigmoid flexure, with a long or short mesocolon, as it may be, is in its most mobile part below the edge of the pelvis, only mounting above this line when distended into the upper pelvis, and that the descending colon, 6 to 12 cm. long, terminates in the iliac fossa, and is adherent to the iliac wall by the absence of peritoneum over one-fourth to one-eighth of its circumference. The colon on each side, while usually attached as described, may be more movable by reason of a mesocolon of variable length. Hernias, therefore, such as are spoken of in the present article as those of the slipped cæcum and sigmoid, really are hernias involving the ascending or descending colon.

---

[1] Read at a meeting of the Practitioners' Society, held January 5, 1900.

[1] Thèse de Paris, 1887.

This latter class of hernias—the subperitoneal, the sliding or slipped hernias of the ascending or descending colon, present difficulties of operative reduction which are not yet satisfactorily overcome, and in which my own endeavors, to be soon narrated, are but tentative, and yet need the corroboration of a larger personal experience and, more important, the confirmation of other surgeons.

Treigney, whom I have just quoted, presents sundry other cases of herniated large intestine which bear more closely on the point now in question. They are as follows:

	Inguinal.	Crural.	Total.
Hernias containing cæcum, end of ileum, and ascending colon	8	1	9
Hernias containing sigmoid flexure .	14	1	15
Hernias containing sigmoid flexure with small intestine.............	7	..	7
Hernias containing ascending or descending colon........	5	..	5
Totals	34	2	30

Of twenty cases in which the ascending or descending colon, alone or accompanied by the cæcum or sigmoid flexure, was involvd a whole sac was found only in seven cases; in five it could not be determined, and in eight the hernia was *par glissement*. This will give some idea of the frequency of this complication. When it is present we have conditions that are prone to bring about such an amount of irreducibility that it demands a special surgical interference, or, if strangulation exists, which is possible, although rare, necessitates the surgeon to relieve only the constriction present and often to forego the intended radical cure of the hernia. The bowels in these instances, in which they have slidden into the hernial sac, are well seen in the diagrams, and are held in position by the connective tissue, which is generally situated on the posterior or postero-lateral aspect, and which from its long subjection to abnormal conditions is often dense and thickened. Pressure under such circumstances accomplishes but little in replacing the protruded bowel in the abdominal cavity, and hence sundry expedients have been resorted to in order to bring about the proper replacement of the intestine.

Before, however, proceeding to the surgical treatment of such slipped or slidden hernias, a word or two concerning their recognition may not be out of order. They are more common on the left side and in males in middle or advanced life. It is difficult to determine their nature before the required surgical intervention. Usually they present themselves with the history, in its early period, of reducibility which is not always amenable to a truss or to taxis, and which soon passes into a permanent irreducible condition. They are usually scrotal when irreducible, and sometimes one can in a left-sided hernia suspect its being one of the sigmoid flexure or descending colon, from the inability to inject per rectum but a small quantity of fluid, or because by such an injection the bowel in the scrotum distends appreciably. So uncertain, however, is the diagnosis, and so often is the slipped large bowel associated with small intestine or omentum in the sac, that time is only misspent in endeavoring to solve the problem except with the scalpel. Only it is to be remembered that in a large irreducible hernia, whether on the left or right side, but particularly on the left side, on account of its greater frequency, it is wiser to make the incision into the sac well to the inner side of the scrotal swelling, and not to carry it too low down, so as to avoid the accident of coming down to and incising an unrecognized bowel deprived of its tell-tale peritoneal protection. On opening the parietal portion of the sac wall, aside from the probably associated omentum and small intestine which can be readily reduced and gotten out of the way, if strangulation be not present, which is first to be relieved, there may be encountered as a hindrance to a possible reduction some enlarged epiploic fringes. Their replacement can be attempted one by one, but even if reduction of these be impracticable or only temporary, as they often reappear when the finger pressure is relieved, their displacement will frequently clear up the field of view so that the postperitoneal condition of the bowel will be detected.

Now, as to the treatment. Very little information on this point is to be found either in text-books or special works on hernia. Ladroitte,[1] in 1882, in a cadaver in which he found a slipped sigmoid hernia, stated that he could bring about its reduction only by completely separating the bowel along its cellular attachment up to the external ring. This published fact attracted but little attention, and but few attempts on this line have been resorted to by surgeons meeting such cases. The majority of these hernias have been unsatisfactorily treated either by being closed up after an exploratory incision, or after a vain attempt has been made to push up the attached bowel toward the external ring and to hold it there by sutures carried from below the intestine to the sides of the ring or through the abdominal wall. Such a plan I was compelled, like others, to use in my first cases, and, owing to my inexperience, the operation resulted in no benefit. Later I employed the separation of the bowel from its subperitoneal bed. This, while generally easy, has at times presented difficulties encountered by other surgeons from the denseness of the tissue, and sometimes, too, the nutrient vessels of the intestine may be so damaged as to bring about its gangrene.[2] Mayo[3] says it is not always wise to attempt this. In the two cases in which the method was resorted to by me, the fear remained that this raw surface of a possibly now greatly thinned and damaged bowel might materially enhance the risk of the operation, and therefore while the procedure permitted the proper suturing together of the internal ring as a part of the due performance of the well-known procedure of Bassini (which I prefer to any), yet I remained not satisfied with the technique of the procedure.

The difficulty of reducing these hernias and, in certain cases, the risk of separating them from their changed resting-place will be appreciated by referring to the collection of cases lately made by Froelich, of Nancy.[4] He has gathered some twenty-one instances, ten strangulated and eleven in which a radical cure was attempted "*à froid*." There were six cæcal hernias, leaving four strangulated sigmoid hernias and nine non-strangulated. Of these Hydenreich had two cases, both followed by fecal fistula. Camplenon's case was followed by an artificial anus. Reverdin, Berger, Terrier, and Froelich all failed to cure their hernias. Terrier and Hartmann reduced the sac and the subperitoneal bowel and closed the ring in two instances. Finally, disturbed by the failure to secure a reduction in two cases, Juillard,[5] of Geneva, boldly resorted to the severe measure of cutting away the protruding bowel and joined the divided intestinal rings by a Murphy button, and with success. He aided the closure of the internal ring and inguinal canal by the additional removal of the testis and spermatic cord. These names of celebrity in the surgical world, exemplify the troubles that environ the satisfactory treatment of these hernias, and their results cannot be called brilliant. The successful outcome of Juillard's case will tempt only a rare repetition.

Anderson[1] gives three cases in which the bowel, although covered with peritoneum, could be pushed up sufficiently to allow of the suturing of the inguinal canal in two instances. In two of his cases the hernia promptly recurred. This looseness of the bowel I have likewise met with.

My records show that I have surgically treated six cases of sigmoid hernia and four cases of cæcal hernia, in one of which the cæcum was in a left-sided inguinal hernia, and in one instance it formed a part of a right-sided strangulated femoral hernia. In two of the sigmoid hernias I resorted to separation of the bowel by a dissection carried on mainly by the finger, and after liberating it and then pushing it up into the abdominal cavity I sewed up the ring and canal and thus completed the operation. I have not been able to trace many of these cases for any long period of time, but I am informed by Dr. Coley that in two or three patients on whom he operated similarly, and whom he had long under observation, they remained cured. In three others I succeeded in pushing back with some effort the herniated bowel and sutured the internal ring, but in a few months the hernia recurred.

In the four cæcal hernias two of them were of the cæcum proper and reducible, having a complete sac; one was found in a femoral hernia; another in a left inguinal rupture. The remaining cæcal and sigmoid hernias, one each, I ventured to attack in the following manner. Thinking that the reduction of the bowel after separation by dissection from the sac into the abdominal cavity was a surgically incorrect measure, as it left a raw and perhaps thinned bowel in the peritoneal cavity, I made an essay, comparatively recently, in these two cases, after freeing the bowel from its bed, to cover the raw surface with peritoneum taken from the sac, as in the manner shown in Fig. 3. This was accomplished by dissecting it up on each side of the bowel, at the top, on a level with or a little above the internal ring, and at the bottom to a short distance below the bowel. The bowel is then loosened, by peeling off with the finger or, if tightly fastened, by cutting or snipping with scissors as widely as possible from it until it is released up to or above the internal ring, which is to be opened widely by retractors or even enlarged by cutting if required to obtain a good view. Then the loosened peritoneum is turned backward and sutured behind the gut as far as practicable. The peritoneal flap should be an ample one, so as to permit to a satisfactory degree the unfolding of the bowel loop and thus avoid kinking, which, however, is rarely of importance in the large intestine. The ring is afterward carefully sewed together after the newly covered bowel is reduced, and if the patient has consented to the justifiable proposition to sacrifice the testis on this side, a radical cure may be reasonably looked for. I cannot but hope that the peritoneal covering that is given by this procedure will, moreover, aid in preventing recurrence, as the direction of any further slipping or sliding is (if the upper incisions have been carried high enough) turned more away thereby from the hernial outlet. In a rebellious case a better exposure could be had by a hernio-laparotomy, as was practised by Terrier and Hartmann in three cases with success. This would allow of a more complete bowel separation and serous investment, and would permit a resort to an intestinal fixation of the intestine above if this extra means of cure was required to prevent any further descent of the bowel. Of the two cases in which the procedure just described was applied, one was of the sigmoid variety (descending colon) and the other of the cæcum (ascending colon), associated in the latter with the small intestine and the appendix in an incomplete sac. There was in neither case any material difficulty in carrying out the idea. In both more than eight months have elapsed since the operation was performed without any recurrence of the hernia, although in the cæcal case this good result was hardly hoped for, as the scrotal swelling was of huge size and debarred the man from his vocation as a waiter. He was informed that the best that could be done for him was to render it possible for him to wear a truss. I may add in concluding that Froelich advises, in cases in which strangulation exists with a slidden bowel, simply to relieve the constriction, to return the caught small intestine and omentum, and to leave the large bowel alone. This should be borne in mind as safe and judicious.

The cases in detail are as follows:

Case I.—Left inguinal hernia; slipped large intestine; operation; reduction; suture of internal ring; cure. W. S——, male, aged sixty years, peddler; left inguinal scrotal hernia of twenty-five years' duration; reducible at first and controlled by a truss; later a hernia appeared in the right scrotum. Entered the New York Hospital January 30, 1885. The hernias were treated by Heaton's injections of tincture of oak bark, which served to keep them up for two months, when they recurred after a severe fall. A second injection was made at his request, but one month later the left hernia recurred. It was then the size of a goose's egg, resonant at its top and partly reducible. On May 22d the sac was opened up to the external ring; the sac was incomplete; its contents were the large intestine, the posterior layer of the sac passing over the intestine. The attachments of the bowel to the scrotal tissue were so lax as to permit the bowel with some force to be pushed back into the abdominal cavity. The sac was cut off as high up as possible toward the internal ring, which admitted the conjoined tips of three fingers. The edges of the ring were sewed together by three silver sutures and the outer wounds closed. He was discharged cured on June 9th. He was seen ten months later, and his rupture had not recurred.

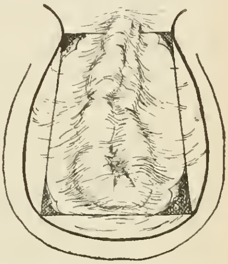

Fig. 3.—Outlioe of Peritoneal Lining of Sac utilized as a flap to cover posterior surface after it has been freed by dissection.

Case II.—Incarcerated sigmoid hernia; operation; incomplete sac; reduction; suture of internal ring. F. B——, male, aged fifty-eight years, priest; left inguinal hernia for twenty-eight years, reducible and controlled by truss until within the past four months. Since this time it has become more difficult to reduce, and he has had more pain and distress in this region. He has lost flesh from the discomfort. The hernia is the size of a cocoanut, and on entrance to the New York Hospital on February 12, 1889, it was in an irreducible condition and the size of a cocoanut and very tender. The incarceration was overcome mainly by gentle taxis after a morphine injection. The internal ring was large, admitting two or three finger tips. Under ether the next day an incision was made from the external ring to the bottom of the sac, exposing the hernia. There was an incomplete sac, the peritoneum passing over and being adherent to a knuckle of the sigmoid flexure, which was at the postero-lateral part of the mass. Six or seven ounces of fluid were found in the sac. With much difficulty the herniated bowel was pushed up into the abdominal cavity, and with a Macewen needle a strong silk ligature was passed through the conjoined tendon and the outer edge of the internal ring and Poupart's ligament, and duly secured. Other sutures were similarly applied to the large ring. The canal was closed by two other stitches, a drain introduced, and the wound closed. Healing was much interfered with by a sharp bronchitis, and the major part of the wound healed by granulation. The patient was lost sight of after leaving the hospital.

---

[1] Brit. Med. Jour., October 29, 1895.

Case III.—Strangulated right femoral hernia containing cæcum and appendix; sac complete; reduction; Bassini's operation. E. H——, aged fifty-five years, seamstress, has had a small irreducible femoral hernia for ten years. Last evening, after a fit of coughing, it became larger and developed the usual signs of strangulation. A long tumor about six inches long and three inches wide was seen in the right groin. Under ether, on December 18, 1894, an incision was made parallel to Poupart's ligament, opening a sac containing a little adherent omentum, two loops of the small intestine, the cæcum, and the appendix, which were free, and which, after nicking the roof of Gimbernat's ligament, were easily reduced into the abdominal cavity. The omentum was tied off, the sac ligatured at its neck, and the canal and opening were closed with chromicized catgut after Bassini's method. On January 19, 1895, she was discharged cured. She was seen a year later, and the hernia had not recurred.

Case IV.—Hernia of sigmoid flexure; complete sac; Bassini's operation; gangrene of testis; sepsis; death. F. I——, male, aged forty-seven years, engineer; admitted to the New York Hospital on December 24, 1894. He had a left inguinal hernia for ten years and had worn a truss for about a year. The hernia was reducible but frequently painful. Bassini's method was used, and on opening the sac omentum and a loop of the sigmoid flexure were seen free in a complete hernial sac. The internal ring was dilated to the size of three finger tips. The omentum was tied off with catgut, and the ring and canal were closed with kangaroo tendon. The patient did badly, with scrotal swelling, which was opened, revealing a gangrenous testis due either to a possible twist, for the epididymis was forward, or, more probably, to a too tight closure of the internal ring. This was among my earliest Bassini operations, when acknowledged inexperience might have led to such a mishap. The testis and cord were removed and the wound was left open and dressed with iodoform. Sepsis prevailed, and the patient succumbed on January 6, 1895.

Case V.—Sigmoid hernia; incomplete sac; reduced by freeing bowel and completing rest of sac by peritoneal flaps; cure. C. W——, male, aged forty-four years, baker; admitted to the New York Hospital on January 23, 1895. He had noticed hernia of the left side for about eighteen months. Lately it has become irreducible and painful, and he could not return the hernia even when it was reducible. Operation was done on January 26th, by the Bassini method; the sac was incomplete; and the large intestine (descending colon) was present behind the peritoneum on the posterior aspect of the sac. The internal ring was enlarged upward for better inspection and manipulation. The herniated bowel was then dissected up from its bed of connective tissue and pushed into the abdominal cavity. The incomplete sac was cut off, and then the reflection of the peritoneum at the internal ring was incised laterally outward and inward so as to obtain a closure of the peritoneal ring behind the intestine pushed into the abdominal cavity. The ring itself and canal were closed *seriatim*. The result was a good one. When last seen, three months afterward, no recurrence was present.

Case VI.—Right inguinal interstitial hernia containing cæcum and appendix; complete sac; Bassini's operation. R. W——, male, aged fifteen years; ruptured himself on the right side, while running two years ago. The hernia was irreducible and did not descend into the scrotum. He wore a truss, but had a good deal of pain. On January 14, 1895, operation revealed an interstitial congenital inguinal hernia, containing the cæcum and appendix free in the main one of two sacs present. Ligature of the sac at its neck and closure of the ring and canal after Bassini's method were resorted to. He was discharged cured. He was seen one year later; no recurrence.

Case VII.—Congenital left inguinal hernia containing cæcum; sac complete; Bassini's operation; cure. G. H——, aged twenty-seven years, engineer, had a hernia of thirteen years' duration, from heavy lifting. Left inguinal hernia was irreducible up to four years ago, the size of two fists. Operation was performed on October 12, 1895, by Bassini's method. The hernia was found to be congenital and to have as its contents the omentum and the cæcum free from adhesions. The omentum was tied off and the cæcum returned. Primary union occurred. He was discharged from the hospital on November 4, 1895; he has not since been traced.

Case VIII.—Left inguinal hernia containing small and large intestines; sac incomplete; reduced by pressure; Bassini's operation; cured. W. I. N——, male, aged sixty-four years; rupture in left groin from a fall received eighteen years ago. Six months later a hernia also appeared on the right side. He was able to wear a truss on the left side for eight years. Since then, now ten years, he could not retain the hernia by any appliance, though both ruptures could always be readily reduced. Both scrotal rings were much enlarged. Under ether both hernias were operated on January 14, 1895, at the same sitting. On the right side the small intestine and omentum were found; four inches of the latter were tied off in sections and removed. Bassini's operation was completed. On the left side a portion of the large intestine was found on the posterior part of the sac covered loosely by peritoneum. As a consequence an incomplete sac was formed. Some small intestine was also present. The sigmoid flexure could with some effort be pushed up into the abdominal cavity so that the sac could be tied off at the internal ring, which was thereupon narrowed by sutures, and the other steps of Bassini's operation were carried into effect. There was no recurrence up to four months later, when the patient was last observed.

Case IX.—Large right inguinal irreducible hernia containing cæcum, appendix, ascending colon, small intestine, and omentum; sac incomplete; plastic covering of separated colon by peritoneal flap; reduction; Bassini's operation. C. H. D——, aged forty-one years, waiter, has had a rupture in the right groin for about eight years without known origin. At first it was reducible, and for its retention he used a truss up to three years ago, when the hernia could not be retained by such means, and he was forced to employ a bandage for support. On entrance into the New York Hospital a hernia as large as a child's head was seen in the right inguinal region, irreducible and largely containing intestine. He was urgent for operative help, as the deformity was apparent through his clothing and deprived him of work. It was candidly told him that such large hernias had greater risk to life, and that only a partial cure could at best be promised. With this understanding, under ether, and using rubber gloves, which is yet the latest fad and not altogether a satisfactory one, the sac was opened March

8, 1899, revealing as its contents small intestine and omentum, with the cæcum and appendix and a part of the ascending colon. The small intestine was reducible. The omentum was adherent in many places. These were tied off, and when duly freed, a large portion was tied off and its stump reduced. This showed very clearly that the sac was an incomplete one, and that while the cæcum and appendix were free and reducible, still the reduction of the ascending colon, which rested at the back and outer part of the protrusion, was impossible by reason of its immobility, it being firmly fixed behind the peritoneum by dense connective tissue. This was carefully divided with scissor snips or else separated by the fingers until the bowel could be easily replaced in the abdominal cavity. Before it was left there, however, the peritoneum from the sac was loosened up and turned backward so as to cover over the raised surface of the bowel, and there held by interrupted fine silk sutures. Then the sac thus completed was sutured at its neck, and the other steps of a Bassini operation were proceeded with. The patient made a prompt recovery, and when seen eleven months afterward no tendency to recurrence was found. He is presented this evening to you for inspection.

Case X.—Sigmoid irreducible hernia; sac incomplete; release of intestine with plastic covering from sac and its reduction; completion of rest of sac; Bassini's operation. M. C——, aged forty-seven years, merchant; referred to me by Dr. De Plasse, January 24, 1899. By lifting a heavy pail of water, thirteen years ago, the patient brought on a left inguinal hernia. This was kept under control by a truss for six years, but since then this has proved comparatively useless. The hernia was partly reducible, found to be scrotal, and in size about three by five inches. Operation was done January 26, 1899. On opening the sac it was seen to be incomplete, and the subperitoneal intestine, which was the lower end of the descending colon, was held *in situ* by somewhat loose connective tissue. The serous coat of the sac was cut on each side a moderate distance from the bowel, which was lifted out with the peritoneal flaps easily from its bed up to the internal ring. These flaps were then passed behind the bowel and sutured together, and the covered intestine was reduced into the general abdominal cavity. It was then seen that the just-covered loop of bowel fell within the abdomen below or beyond the region of the internal ring. The ring then completed by this little plastic effort was duly closed by sutures, and the remaining steps of the ordinary Bassini operation completed the case. It progressed uneventfully. He was lately seen, and has had no recurrence now nearly a year after the operation.

Of these ten cases, six were sigmoid hernias of which there was a complete sac containing an ordinary loop of the sigmoid with a long mesentery which allowed of its ready reduction. Five, however, had slidden out behind the peritoneum and required in three cases only firm pressure to force the bowel back into its place in the abdomen. In the two remaining cases the bowel was freed from its bed, then covered with the peritoneum of its incomplete sac, and finally reduced. Four other cases were of the cæcal variety. Three of these had a complete sac, and the hernial mass was readily reduced. In the remaining case the intestine (ascending colon) was freed by dissection and covered by peritoneum from the incomplete sac and successfully reduced.

Heidelberg University has opened its doors to the other sex. Women can now attend the medical lectures and examinations upon the same footing as the men.

THE CLINICAL USES OF THE SPHYGMOGRAPH.[1]

By R. VAN SANTVOORD, M.D.,

NEW YORK.

On considering how I might best fulfil my promise to the president of the Academy in the preparation of a paper on the clinical uses of the sphymograph, I decided to restrict myself to [illegible] analysis of my own results obtained b[illegible] a single instrument, that of Dudgen, dur[illegible]e last fifteen years. As the sphygmograph is an instrument which is not in general use among physicians, it will be advisable to recall briefly some of the elementary facts which must be borne in mind to order to interpret its tracings.

A sphygmogram is an approximately accurate record of the variations in arterial tension. Arterial tension is the lateral thrust of a column of fluid contained in a closed tube and compressed between the force of the ventricular contraction and the post-systolic arterial retraction on the one hand, and the resistance to the flow of the fluid on the other. This resistance consists mainly in the friction of the blood on the walls of the vessels, and is obviously directly proportioned to the velocity of the current. Gravity is a second important factor, which may, however, be neglected in the present inquiry, as all the tracings to be presented were taken on the radial artery with the patient sitting with the arm dependent and flexed at the elbow or horizontal as he lay in bed.

The factors which influence the rapidity of the blood current during the different periods of the cardiac cycle are the amount of blood thrown into the aorta at each systole of the ventricle, the rapidity of the heart action, the condition of the aortic valves, the elasticity of the vessels, the degree of contraction of the capillaries and arterioles, and, under exceptional circumstances, the pressure in the veins.

It is commonly stated that the amount of pressure on the spring of the sphygmograph required to develop a tracing of maximum amplitude, like the amount of pressure required to stop the pulsation of the vessel beyond the point of compression, is a measure of the absolute arterial tension, *i.e.*, the tension per unit of surface of the vessel.

This is true only when comparison is made between vessels of equal calibre. Marey found that the vessel supplying an aneurism could be easily compressed by a moderate amount of force, whereupon pulsation in the aneurism would cease. The same amount of pressure applied to the aneurismal sac produced no appreciable effect, a vastly greater amount of directly applied force being required to suppress its pulsation. The explanation of this difference is that the transmission of pressure through fluids under tension is equal in all directions, each unit of surface being acted on by the same distending power. The result is that the sac of the aneurism, which at any part of its diameter contains a larger number of units of surface than a corresponding section of the vessel, requires a correspondingly greater force to compress it. This same law obviously applies to radial arteries of different calibre. If we have two vessels, each having the same pressure to the unit of surface but one having twice the internal diameter of the other, it would take double the pressure to obliterate the former than it would the latter. Again, if in these two vessels we have in the larger only half the pressure to the unit of surface present in the smaller, it would require the same pressure to obliterate either. To a palpating finger the two latter vessels would seem to have the same tension, although the absolute tension in the smaller would be just double that in the larger. In the former instance of equal units of tension in vessels of unequal size, the large vessel, requiring more force to compress it, would to the finger appear to be of far higher tension.

---

[1] Read before the New York Academy of Medicine, December 21, 1899.

Now in order to develop the tracing of the artery, the pad of the recording instrument is pressed down upon it until it is transferred from a cylinder to a body of elliptical section. The excursions of the lever are caused only to a very slight extent by actual dilatation of the vessel. They are caused mainly by the rising and falling of the artery as it approaches and recedes from its normal cylindrical shape under the variations of tension which occur at different parts of the cardiac cycle. If the pressure of the pad exceeds the sum total of the units of tension which are brought to bear upon it, the calibre of the artery will be obliterated and no tracing will be made. If the spring pressure is too light, the lever would be affected only when the tensile force has partly expended itself, and the tracing will be wanting in amplitude. The necessary pressure on the spring to produce the largest amplitude of tracing lies between these two extremes, and what this tension should be depends not alone on the tension per unit of square surface, *i.e.*, the absolute tension of the artery, but upon this combined with the number of units acting on the pad. In other words, a tracing of maximum amplitude developed under a pressure of five ounces on a small artery represents a higher absolute tension than a tracing of maximum tension developed under the same pressure in a large one. Allowance must be made therefore for difference in the size of the vessels in estimating the significance of the amount of pressure necessary to develop a tracing. The form of the tracing will, I believe, give a far more accurate record of the absolute tension of the vessel than the amount of pressure required to develop it; rapid and extensive variation in tension being indicative of slight resistance and low absolute tension; slight variation in tension being indicative of great resistance and high absolute tension. Results obtained by instruments like the sphygmomanometer of von Basch, which measure tension by indicating the amount of pressure necessary to exert on a vessel to prevent its pulsation being felt beyond the point of its application, are open to three objections: (1) It is difficult, at times impossible, to determine with any approach to accuracy just when pulsation has ceased; (2) the measurement of the necessary pressure is of value only if we know also how large a surface we are compressing; (3) the instrument measures only the highest point of pressure existing during the cardiac cycle and tells us nothing of its variations, which, as will presently be demonstrated, are highly significant.

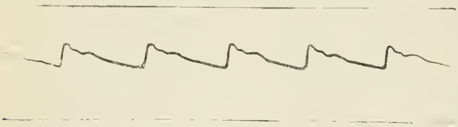

Fig. 1.

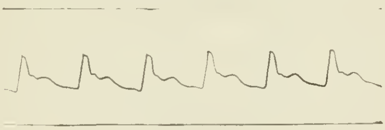

Fig. 2.

I will now present a series of tracings showing the form of the sphygmogram in the healthy adult under different physiological conditions. From these we will pass on to pathological variations.

I present here a tracing (No. 1) taken from a healthy young adult who had been sitting quietly for some time previously. The ascent of the tracing is nearly vertical; the primary wave is slightly blunt-pointed. The next most prominent wave in the tracing, the dicrotic impulse, corresponding to the period just succeeding the closure of the aortic valves, is marked and still more rounded. A third, known as the tidal wave, is indicated between these two, and is below the level of a line drawn between the dicrotic notch and the summit of the primary wave. One or more undulations will often be manifest in the portion of the line of descent following the dicrotic wave. There will be variations in the appearance of the tracing according to the instrument used; the lever of the Marey type moving in the arc of a circle; the recording needle of the instruments of Pond and Dudgen playing to and fro in a straight line. The relation between the magnifying power of the instrument and the rapidity of the motion of the paper must also be considered in contrasting the work of different instruments.

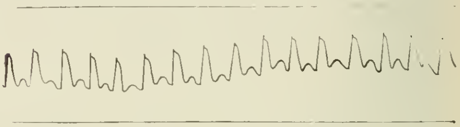

Fig. 3.

The illustrations which I show are copied on the same scale and with substantial accuracy from sphygmograms taken with the same instrument and with the paper moving with the maximum velocity of the clockwork, so that these considerations do not concern us in comparing them with each other.

The second tracing shows diminution of tension after a meal in the same individual from whom the first was taken. The primary wave has become much more pointed, the dicrotic undulation more marked, and the dicrotic notch, whose position in the tracing is the best indication of post-systolic tension, occupies a lower level.

The third tracing was taken from the radial artery of a perfectly healthy young man immediately after several minutes of active work on a stationary wheel in a gymnasium. The spring pressure was two and one-half ounces.

A tracing of the pulse at the same pressure just before the exercise showed a normal sphygmogram.

In accordance with the law explained at the beginning of the paper, the pressure of two and one-half ounces on the artery expanded during exercise represents a lower tension than the same pressure on the artery when relatively contracted during rest. The long pointed primary wave, the disappearance of the tidal wave, the low position of the dicrotic notch, the marked dicrotic impulse and great increase in rapidity of the pulse and amplitude of the tracing, are characteristic of low tension in a normal vascular system due to relaxation of the peripheral vessels, produced in this case by a physiological cause.

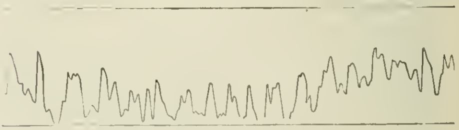

Fig. 4.

The tracing (Fig. 4) taken during the actual work shows the same characteristics, but is exceedingly irregular owing to the unavoidable muscular jerking and some irregular action of the ventricle.

Fig. 5 represents a type of high tension taken from the same subject as the preceding, during an attempt to raise himself from the floor with one hand. The first few waves show the same characteristics as the preceding, but the general line of the tracing runs up rapidly on the paper, showing increase of tension, and the amplitude of the individual waves diminishes greatly. The explanation is that with the effort the glottis was closed and the muscles of the trunk rigidly contracted. The pressure in both thorax and abdomen being thereby greatly raised, the entrance of the venous blood into the great vessels of the trunk was impeded, venous tension markedly increased, and this acting backward through the capillaries caused a corresponding increase of pressure in the arteries, the peripheral vessels still remaining widely open.

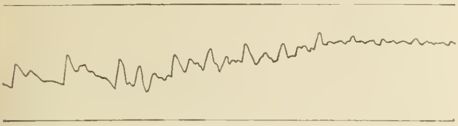

Fig. 5.

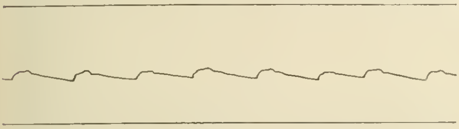

Fig 6.

The sixth tracing was taken from a case of tetanus and shows exceedingly high tension in elastic vessels. The line of ascent is gradual, the primary is lower in level than the tidal wave, both being, in common with the dicrotic, but faintly indicated. The dicrotic notch is as high in the tracing as the primary wave.

The seventh, as proved by autopsy, taken from a case of diffuse nephritis, predominantly parenchymatous, in a boy, shows these same characteristics in a less pronounced degree, the ascent being not so gradual, the primary waves in common with the tidal being more pronounced and on the same level, and the dicrotic notch lower in the tracing.

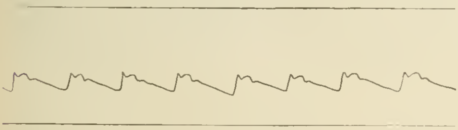

Fig. 7.

These cases may be described as cases of continuous high tension.

One rule given for the interpretation of a sphygmogram is to consider every tracing as above the normal in tension in which the tidal wave is above a line drawn from the dicrotic notch to the summit of the primary wave. These two tracings by this test, it will be observed, are of decidedly high tension.

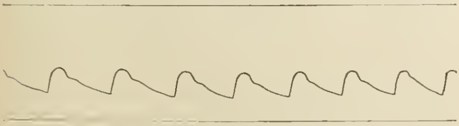

Fig. 8.

The next (eighth) sphygmogram was taken from a woman of eighty-three years in good general health but for the infirmities of age, whose radials were somewhat rigid and tortuous. Primary and tidal waves are fused together in a rounded summit; the dicrotic notch is at a slightly lower level than in the tracing No. 7, which shows moderate high tension in elastic arteries, and the dicrotic impulse is but slightly indicated. As Marey has stated, the systolic portion of such a tracing bears a strong resemblance to the tracing taken in the ventricle during its contraction, and represents the transfer of the ventricular impulse to the radial artery through the rigid vessels with but slight modification. Owing to the slight retractility of the great vessels the amount of blood forced into the periphery during cardiac diastole is less than normal, dicrotism is less, velocity falls, but the tension does not suffer a corresponding diminution because of the resistance offered by the inelasticity of the vessels beyond the point at which the sphygmogram is taken. The tracing may be described as one of high systolic and relatively low post-systolic tension, a combination which is typical of arteries which are less than normally elastic.

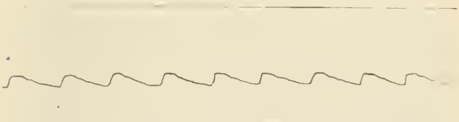

Fig. 9.

In cases which we meet in practice in which diseases of the vascular system and of the kidneys are found in various combinations, we have frequently the combined effects of inelasticity and increased peripheral resistance manifest in the tracing.

The following (No. 9) was taken from a stout lady, aged fifty-two years, who suffered from considerable dyspnæa. The tracing is of small amplitude. Its almost flat top without indication of primary and tidal waves indicates lack of elasticity, while the very high position of the dicrotic notch shows very high tension in the post-systolic portion. Moreover, it took a pressure of five ounces to develop the tracing. This pulse felt very small and weak. I would not have been able to recognize its nature without the sphygmograph. The pressure of five ounces on a very small artery, required to develop this tracing, was significant of absolute high tension.

The next tracing (No. 10) shows a flat-topped systolic and rather low tension post-systolic portion indicative of loss of elasticity. As the artery was large, the pressure (five ounces) necessary for its development was not significant of so much absolute high tension as in the last case. It was taken from a patient suffering from a recent cerebellar hemorrhage, whose urine presented at the time nothing abnormal. Retinal hemorrhage occurred at this time. Hyaline casts were found in the urine two years later, albumin after five years had elapsed, the quantity of urine gradually increasing and the specific gravity falling. He died, finally, from the giving out of his heart, more than nine years after his apoplexy.

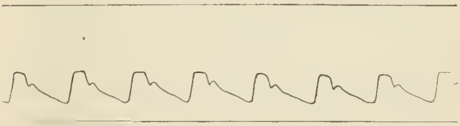

Fig. 10.

The next tracing (No. 11) was taken from a lady, aged sixty-four years, who suffered from dyspnœa and attacks of syncope, in one of which she died a month later. Her pulse was beating at the rate of thirty per minute. The systolic portion shows the rounded wave of inelasticity, and the dicrotic notch is very high on the tracing, showing enormous peripheral resistance.

Under the influence of nitroglycerin, the following modifications resulted:

(No. 12.) The rounded top of the systolic wave became almost flat, recalling the types last shown, the plateau being preceded by a small, sharp elevation. The dicrotic notch was lower in the tracing and the dicrotic wave more accentuated. This sharply pointed elevation at the summit of the tracing is to be explained as being due to an oscillation of the spring of the instrument. In inelastic vessels, especially when the tension at the end of the systole falls below a certain point, the advancing ventricular impulse is so sudden as to act as a water-hammer and cause a sharp oscillation of the spring of the instrument. This is a very frequent feature in tracings from inelastic vessels at medium and low average tensions. In elastic vessels this water-hammer oscillation occurs only in cases of extremely low peripheral resistance with a fairly strong ventricle.

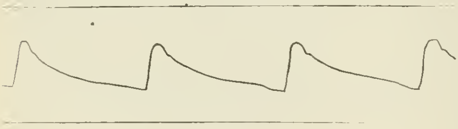

Fig. 11.

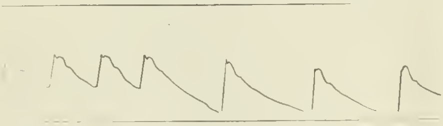
The next tracing (No. 13) to be considered is an undulation from this same sphygmogram, but in a place where three slow beats at the rate of about forty per minute followed others, one of which we have just examined, which were at the rate of seventy per minute. The slower beat allows the artery more fully to empty itself before the next systole. We get greater amplitude, less absolute tension, as shown by the downward curve of the general line of the sphygmogram, and the plateau back of the water-hammer oscillation is converted into a somewhat obtuse point, all showing the effect of a still greater lowering of tension in this same vessel.



Figs. 12 and 13.

In the next tracing (No. 14) one of the larger units from a very irregular sphygmogram obtained from a man with rigid and tortuous arteries, suffering from pneumonia, we see the result of a still greater reduction of peripheral resistance on a tracing taken from an inelastic artery. The cardiac systole is represented solely by a sharp point, the plateau having disappeared entirely. The tracing still shows the inelasticity of the artery in the relatively high position of the dicrotic notch, which in the tracing of a normal, very low tension pulse with a somewhat corresponding systolic wave, would be near the base line and in the relatively slight development of the dicrotism.

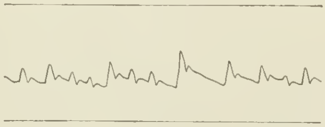


Fig. 14.

The next tracing (No. 15) from a case of pneumonia in a man, aged sixty-two years, shows a still lower tension of the same character, except that there are two jagged water-hammer oscillations at the summit instead of one, the blow being so sharp and the pulse collapsing so suddenly that a second slight oscillation occurred before the spring of the instrument followed the receding wave.

Tracing No. 16 shows a water-hammer apex betraying inelasticity of the artery, a slightly indicated systolic elevation, a dicrotic notch midway in the tracing and a slightly indicated dicrotic wave. The tracing is obviously one of rather low tension in an inelastic artery. Low tension indicates diminished velocity and consequent diminished resistance to the blood current, and may be produced, as in examples given above, by arterial dilatation with a normal ventricular output, in which case we have a large blood stream flowing slowly. Or it may be produced by diminished ventricular output with normal or even contracted or inelastic arteries, in which we have a small blood stream flowing slowly. Other things being equal, the amplitude of the tracing will be greater in low tension, due to peripheral relaxation of the vessels, than in the same condition due to ventricular failure, but no absolute conclusions can be drawn in comparing the amplitude of one tracing with that of another, because differences in the size of individual arteries and in the adjustment of the recording instrument are factors having a material influence on the amplitude. In this case, however, the radial was very large and somewhat hard. It would be safe to infer, therefore, from the moderate amplitude of the tracing, supposing it to be properly taken, that the low tension was due to ventricular failure. The patient in question was a man of large frame, formerly of great physical strength but suffering from cardiac dilatation, chronic nephritis, and acute bronchitis. He moved about with difficulty on account of dyspnœa and weakness. The chief point of interest for our present point of view was that to the finger this pulse gave the impression of exceptional force, so much so that the patient, himself a physician, remarked that there could not be anything much the matter with his heart because his pulse was so strong. The explanation was that on account of the very great size of the artery the finger had to overcome the resistance of a much larger surface under tension than in the case of a vessel of normal size. This combined with the comparatively sudden impulse of a low tension pulse and the resistance of a somewhat hardened artery, gave the misleading feeling of strength and high tension to the pulse. The man's condition proved that the sphygmogram was right and the impressions produced upon the finger were absolutely misleading.

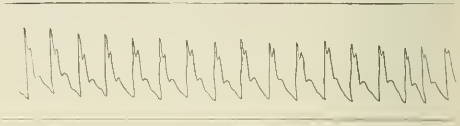

Fig. 15.

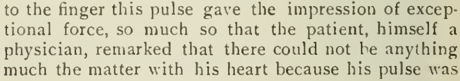

Fig. 16

One of the chief uses of the sphygmograph in actual practice consists in the ability it gives us to detect high arterial tension in the earlier stage. This high tension in the majority of cases shows itself in the flat-topped tracing similar to that shown in Fig. 10, and is indicative of arteriosclerosis chiefly, though this is obviously combined in some cases, as in Fig. 9, with contracted arterioles. In many cases the sphygmogram has given me information which I was not able to obtain with my finger. It is hardly necessary to recall the fact, long since demonstrated especially by Mahomet, that this high tension often precedes recognizable indications of lesions of the kidneys by a long interval of time. In a case reported above it was two years before granular and hyaline casts were found, and five before albumin appeared in the urine, that marked inelasticity of the vessels was demonstrated by the sphygmograph. The combined cardio-vascular and renal lesions require often not one or two, but five, ten, or more years for their full development.

Back of persistent high tension, back of the lesions of heart, vessel, and kidney, are the little understood changes in metabolism due to hygienic errors in eating and drinking, work and worry, exercise and recreation, modified more or less by intercurrent infections, acute and chronic. When the damage to the vascular system and the kidneys has become so great that they no longer are able to respond fully to even the most restricted physiological demands, we can do but little for our patients. In the earlier stages we can do much.

It has often astonished me to see for how long some patients, who are willing and able to take care of themselves, especially women in comfortable circumstances and leading sheltered lives, will remain in fair general health in spite of marked evidence of serious renal and vascular disease. It is hardly necessary to insist upon the great value of this early warning of coming danger. The absence of high tension does not, however, necessarily exclude the existence of serious renal lesions, especially those of parenchymatous nephritis in a subacute stage. One of my records shows a normal, rather low-tension tracing in a case of parenchymatous nephritis apparently of malarial origin. The patient from whom was taken the tracing showing high tension, in a normally elastic artery (No. 7) during a remission of the disease, later had a normal pulse. Autopsy showed a diffuse nephritis predominantly parenchymatous.

The effect of high arterial tension in producing cardiac overwork has long been recognized. In a paper[1] before this Academy, read last April, I presented the reasons for believing, as demonstrated experimentally by Romberg in 1895,[2] that excessive low tension such as is present in pneumonia and other acute infectious maladies is also a source of cardiac strain, my study being confined to acute lobar pneumonia. Although the resistance to be overcome at each ventricular systole is much below the normal, the increased rapidity of the heart-beat rendered necessary in order to maintain a capillary tension adequate to the needs of the body, and to secure a proper distribution of the blood in all the organs irrespective of gravity, more than offsets this advantage.

The records of other observers were confirmed in demonstrating the existence of this low-tension pulse by the use of the sphygmograph.

An interesting fact in this connection is the great tolerance by these patients of digitalis. In a number of cases on my service in the Harlem Hospital I demonstrated this, using the U. S. P. infusion, not the weaker one employed by Petresco, who has so strongly advocated the treatment of pneumonia by large doses of the drug. The connection between this tolerance and the low peripheral resistance was strongly indicated by the fact that the only patient who showed marked intolerance of the drug, as evidenced by irregularity of the pulse after its administration, was an old man with rigid arteries, *i.e.*, with one factor in peripheral resistance which dilatation of the arterioles could not overcome. My experience confirms Petresco's records of very slow heart action during convalescence after this treatment.

Fig. 17.

My records contain cases suggesting that excessively low arterial tension may be an important factor in chronic as well as in acute diseases. The tracings in cases of exophthalmic goitre are characterized by low tension. In one instance the administration of ergot and bromide of potassium, given with a view of bringing up the tension, was followed by the rapid improvement and recovery of the patient. One case proves nothing, of course, but it is suggestive.

A case of rapid heart with a low-tension tracing suggestive of both relaxed vessels and weak ventricle, in which there was no other indication of Graves' disease, was not much affected by ten-drop doses of tincture of strophanthus, but was markedly helped by twenty-five- and thirty-drop doses continued for a long period.

This experience recalls the corresponding tolerance of digitalis in pneumonia. Most authorities agree in stating that digitalis is of little use in Graves' disease, referring doubtless to the ordinarily used amounts of the drug. This case suggests the possibility that in Graves' disease, as in pneumonia, there may be a tolerance of the drug requiring a much larger dose to produce a given effect than is necessary in cases of average pulse tension.

A lady who had long been exposed to trying conditions in life, came to me complaining of prostration and flatulent dyspepsia. Her sphygmogram (No. 17) showed inelastic arteries and marked post-systolic low tension. After improving greatly under treatment she presented the following tracing (No. 18). The contrast makes it not at all improbable that abnormally low tension due to some passing auto-intoxication was embarrassing her heart and giving rise to the feeling of weakness complained of when she was first seen.

I had from time to time been much puzzled by complaints of faintness from patients, quickly following the administration of nitroglycerin. In these cases, what probably happened is that owing to an overdose, or to the more than usually rapid absorption of a dose generally tolerated, the arterial tension was carried so far below the middle point, at which the heart does its work with the least effort, that it became embarrassed in the way above indicated.

Fig. 18.

The conception of abnormal relaxation of the peripheral vessels as a factor in causing cardiac embarrassment has received but little attention.

These cases are offered to illustrate the importance of more definite study of this condition in the future, and of the value of the sphygmograph in demonstrating its existence.

[2] Berliner klin. Wochenschrift, Nos. 51 and 52, 1895.

The last series of sphygmograms which we will consider are those produced in cases of aortic-valve lesions. Leakage of the aortic valve gives rise to post-systolic low arterial tension, which will be greater or less according to its amount.

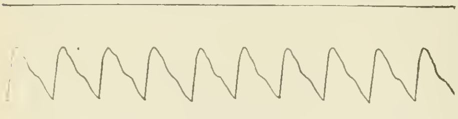

Fig. 19.

Tracing No. 19, taken from a boy aged eighteen years, with marked cardiac dilatation, shows a primary wave obtusely pointed, a dicrotic notch far down in the tracing, and slightly indicated dicrotic impulse. The last feature in a tracing, showing, as this does, an elastic artery, is indicative of considerable aortic leakage. In an elastic artery with competent aortic valves and as low a post-systolic tension as is indicated by the position of the aortic notch, the dicrotic wave would be much more pronounced than it is in this instance.

Tracing No. 20 shows a slightly high-tension sphygmogram of normal type. As the dicrotic impulse is fully developed, the murmur must have been due to a very inconsiderable leakage. Mitral regurgitation and great hypertrophy of the left ventricle were also present.

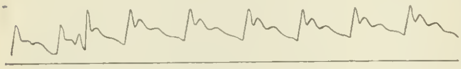

Fig. 20.

The next tracing (No. 21), taken with a spring pressure of three ounces from a subject with marked cardiac hypertrophy but no subjective symptoms, shows systolic high tension with rounded indications of primary and tidal waves and marked post-systolic low tension, with slight indication of the dicrotic impulse. This shows a well-compensated leakage of considerable extent in elastic arteries.

In the next (No. 22) the rounded summit of inelasticity appears, and the post-systolic low tension is obviously due to two factors, viz., rigidity of the great vessels and aortic-valve leakage. Three months later, this patient's pulse had increased from 80 to 126, and his compensation had markedly failed. His sphygmogram (No. 23) then presented two jagged water-hammer oscillations at the summit, which we have already learned to associate with falling tension in rigid arteries, and the dicrotic impulse became much more marked. This latter circumstance would seem to show that rigidity had a greater share than leakage in the suppression of this impulse in the earlier sphygmogram, as the effect of rigidity in suppressing dicrotism is in a measure offset by diminished tension, as may be seen by comparing tracings 17 and 18, in which inelasticity existed unaccompanied by leakage. The autopsy of this case, made some months later, showed a flabby dilated and hypertrophied heart, smooth, evenly contracted, and somewhat thickened aortic-valve leaflets, and a very atheromatous and dilated aorta.

Fig. 21.

Tracing No. 24 shows a sharply pointed wave falling quickly to the base line without indication of either dicrotic notch or impulse. In a pulse of so extremely low tension we would hardly be justified in concluding that the water-hammer oscillation was due to inelasticity of the vessels, because even in elastic vessels such an oscillation may be produced when the tension drops excessively. The tracing falls away with great suddenness, showing no trace of tidal wave or dicrotic notch or impulse. A very short ventricular systole and great leakage of the aortic valves may be inferred. It was taken twelve hours before death from a man in whom an autopsy showed enormous left ventricular hypertrophy and dilatation associated with extensive fibroid changes in the heart muscle, dilatation of the aortic orifice with shrunken and thickened valve leaflets, and an aorta which was greatly dilated and atheromatous, the roots of the great vessels being also markedly affected.

Fig. 22.

Broadbent presents in his book on the pulse a number of tracings of varying form representing aortic regurgitation, taken by different observers with different instruments, as proof of the unreliability of the sphygmograph. I have presented a still more widely varying set of tracings from patients with aortic regurgitation taken by the same observer with the same instrument. I hope that the above analysis has made it clear that these differences, instead of showing any fault on the part of the instrument, are in reality valuable and easily interpreted records of the varying conditions present in individual cases.

Fig. 23.

The next tracing (No. 25) was taken from a case of marked aortic obstruction, the characteristic feature of which is the very gradual line of ascent indicative of the slowness with which the blood was forced past the narrower aortic orifice into the vessels. The pulse in this case gave a misleading impression of extreme weakness owing to the gradual distention of the artery. The sphygmogram corrected this false impression and indicated the fact that the systolic murmur over the base to the right of the sternum was due to very considerable narrowing of the aortic orifice.

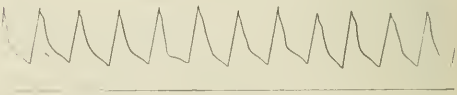

Fig. 24.

This tracing resembles in character No. 26, which was taken from the left radial of a case of aortic aneurism, No. 17 showing the right. In this case marked difference was detected only on an occasion when the aneurismal sac was temporarily distended by a paroxysm of coughing.

The utility of the sphygmograph in giving a record of the various irregularities of the pulse associated with myocardial disease, with or without mitral lesions and with certain toxæmias, may be mentioned, but exemplification would hardly be profitable in this place.

Fig. 25.

The individual pulse waves show nothing characteristic of these conditions, and in so far as they give evidence of deviations from the normal they are to be analyzed in accordance with principles already sufficiently illustrated.

A general objection to the utility of the sphygmograph has been the alleged uncertainty of its results: that different observers working with the same or different instruments fail to get analogous tracing in supposedly parallel cases, or even in the same case. Some of these objections, such as that of Broadbent above quoted, are certainly not valid, as the observed differences are based upon corresponding variations in the factors which influence the tension of the arteries in the successive periods of the cardiac cycle in the individual case, as I have illustrated in a number of instances. It is nevertheless true that faulty application of the instrument may give unsatisfactory or misleading results. In small arteries of high tension failure in the use of sufficient pressure on the spring results in getting a tracing of too small an amplitude for analysis.

Fig. 26.

In many cases of medium-sized vessels and tension, however, variations in spring pressure often produce surprisingly uniform tracings differing only in amplitude. Every degree of tension in the artery requires a certain degree of pressure on the spring for its fullest development in the tracing. Too feeble a spring pressure fails to develop fully the strong portions of the tracing and gives undue prominence to the weak. Too strong a pressure tends to suppress more or less completely the weaker parts of the tracing and give undue prominence to the strong.

Fig. 27.

In tracing No. 28, taken from a case of pneumonia with a pressure of two and one-half ounces, the systolic portion is strongly marked, the dicrotic wave is almost suppressed.

Tracing No. 29, taken from the same case, with a pressure of one and one-half ounces, shows a less marked systolic wave and a very well-marked dicrotic impulse. In this case, if the rule had been followed to accept the tracing taken when the spring was at that degree of pressure which gave the largest excursion of the recording needle as the nearest representation of the truth, it would have been an obvious error. The only method of getting with any degree of certainty a tracing with that medium pressure on the spring which does not sacrifice the strong to the weak portions, or *vice versa*, is to take a series of tracings, each not necessarily occupying more than a third or fourth of a slip of the usual length, with a gradually increasing pressure on the spring. As with each increase of pressure on the spring there must be a corresponding increase of the tightness of the band which fastens the instrument to the wrist, the addition of two small tourniquets on this band, one on either side of the sphygmograph, is of very great importance in securing accurate results, as by their use the band may be tightened or loosened without lateral displacement of the instrument. The effect of too great pressure on the spring in another type of tracing is illustrated in Figs. 30 and 31. The first (No. 30) was taken at a pressure of three ounces. The second (No. 31), at a pressure of four ounces, shows the suppression of the first portion of the tracing and a diminution of amplitude in the tracing as a whole.

Fig. 28.

Fig. 29.

Fig. 30.

I have so often proved that this peculiar nicking out of the first portion of the tracing is an artefact that I am sure that any sphygmogram presenting such a peculiarity may be rejected as imperfect. It will be observed that the water-hammer oscillation is included in the suppressed part of the tracing. The spring had become too stiff, relatively to the force of the pulse, to yield to the blow.

On the other hand, in taking a series of tracings at gradually increasing pressure the water-hammer oscillation may be absent in the tracings taken with a small amount of pressure upon the spring, and appear as the pressure increases. The tracings in which it appears under these circumstances will usually be found to be of greater amplitude than those taken at a lower spring

Fig. 31.

tension, and these pulses are usually of considerable tension in inelastic arteries. The explanation of its absence in these lower spring tension tracings is that the spring had not yet been pressed down upon the artery enough to get the full force of the blow.

In tracing No. 32, at a pressure of three ounces no water-hammer oscillation is evident. In tracing No. 33, at a pressure of four and one-half ounces, it is obvious.

Fig. 32.

Failure to apply the middle of the pad of the instrument exactly over the artery results sometimes, especially in large vessels of low tension, in obvious distortion of the tracing. The variety which I have been able distinctly to recognize resembles that produced by too great tension of the spring. Apparently the instrument is tilted to one side as the artery rises, and the vessel impinges on the rigid projection at the side of the spring. As a consequence, the tracing is partially suppressed.

Finally, it must be confessed that we find occasionally arteries that are so small or so deeply placed that no satisfactory tracings can be obtained. Also, when the ventricular action becomes very feeble the variations in the tension of the artery may be too weak to overcome the inertia of the instrument sufficiently to give a tracing of any value. In spite, however, of these confessed limitations and sources of error a review of a considerable number of tracings taken by me during the last fifteen years shows so constant a recurrence of certain types whose readings harmonize with the clinical history of the cases and with the post-mortem findings, when it has been possible to obtain autopsies, that I have come to regard the sphygmograph as of very considerable practical value in diagnosis, and its sources of fallacy no greater than in many other methods of investigation which we would not think of discarding.

THE PHYSICIAN AS A FACTOR IN EDUCATION.

By FRANK OVERTON, A.M., M.D.,
PATCHOGUE, N. Y.

Dr. Holmes, in his "Autocrat" papers, says that each individual is a trinity of three distinct personages: First, he is what he thinks himself to be; second, he is what others think him to be; and third, he is what he really is. What medical science actually accomplishes is in marked contrast with the notions which are often held even by educated people. This paper deals with the second person of the doctor's trinity, or with the opinion which the public have of medical matters. It indicates a few of the many points in which they might be educated by the medical profession with benefit both to the community and to the profession itself.

A little of a man's knowledge comes from reading and study; but by far the greater number of his ideas are received from conversation with his parents or associates. In other words, the most of each individual's knowledge is as purely traditional as it was in Homer's day. Fifty years ago the science of medicine was crude in its simplicity, and could easily be acquired through a short apprenticeship in a doctor's shop. As in other sciences, what were then professional secrets have now become common knowledge. But many theories which have long since been discredited by the profession still linger in the popular mind, and are perpetuated by tradition, as parents tell them to their children, and ignorant nurses to their patients. Within a generation medicine has advanced so rapidly that even an educated layman can scarcely follow a modern interpretation of a simple disease. The laity, however, are familiar only with the medicine of a generation ago, and they are ready to act on their erroneous ideas.

In the treatment of every patient the physician will be plied with questions which indicate the survival of ancient ideas of physiology and pathology. Has he taken cold? Will it lead to fits? Would a plaster draw out the pain? Can't you give something for his blood? Will it do to heal up the sore? Would it not be better to wait for the abscess to open itself? These familiar questions are relics of ancient medical thought, which survive only by tradition. The physician in his hurry or annoyance assents to every question, and thus unwittingly lends his sanction to erroneous and often untruthful impressions. While these antiquated ideas may not directly affect the patient's recovery, they put a conscientious physician in a dilemma. If, for instance, he says that a patient suffering with boils does not have bad blood, he loses his reputation as a diagnostician; and if he professes to give a blood medicine, he loses his own self-respect. As long as a recent graduate thinks only of the needs of his patient, his practice is chiefly in personal economy; but when the struggle for existence compels him to look chiefly after their preferences, he gains a profitable reputation for experience in purifying the blood, opening the pores, drawing out pain, and bringing abscesses to a head. This is business, but it does not seem quite professional that we need to deceive the community by our words, even though our diagnoses and prescriptions are scientifically correct.

Along with treatment, patients usually ask concerning the nature of their diseases, and the reasons for treatment. It is to our advantage to give them this information, and especially so since it is expected. There need be no fear that in a few moments any one can wrest from us secrets whose acquisition cost us months of close application. Even though some should gain a few practical ideas, sickness will not cease, for human nature is ever the same, and the doctor himself sometimes transgresses the laws of health.

The meaningless diagnosis that the "system is run down," and that a "tonic" will permanently restore it, is usually satisfactory to the patient, and profitable to the physician. This belief seems harmless, but it is really only another phase of the fable of the fountain of eternal youth. The public have outgrown these nursery tales, and can now bear the strong meat of science. Let us teach the great principle of self-poisoning from the retention of waste products; show their origin in errors of diet, ventilation, and exercise; tell of their expulsion ordinarily through the skin, kidneys, liver, and bowels, and in an emergency through the stomach also; give the action of drugs on these organs; and explain nature's remedial measures of refusing food or of rejecting that which is already feeding the poisons. Let us make plain the nature of each infectious disease, and the manner of its transmission; and impress the infectious origin of all "matter" and abscesses, and the necessity of surgical measures in their treatment. It is time that these and similar truths should enter into popular thought.

How shall we instruct our "nervous" patients? The more they know the more fearful they become, until it would seem as though any instruction at all would be unpractical. This class of patients are usually intelligent, and talk much about their ailments and the doctor's opinions. Many erroneous impressions are fixed by the innocent deceptions which the physician is almost compelled to practise in order to pacify them. For instance, the popular confidence in "something to quiet the nerves" is perpetuated in this way. These patients are impressed by the personality of a healer rather than by any intrinsic value in his therapeutic measures. Hence they are the willing followers of Christian scientists. faith curists, advertisers of nostrums, and of any one else who has the self-assurance to claim unusual powers. Of course a few are completely relieved, and their positive testimonials outweigh the negative opinions of the hundreds who are duped. If only for our own interest, we should explain the scientific principles by which these cures are effected, and that, under other names, they are being applied constantly with but a small percentage of failures.

Abstract physiology is taught in all public schools, but applied physiology and the physiology of sickness is learned only from the doctor. No matter what the schoolbooks may teach, the doctor's opinions are believed and acted upon. The proper administration of a prescription presupposes a certain amount of knowledge on the part of the attendant. Unless the medical education of the people is up to the times, we will be handicapped in our treatment. Both self-interest and the public good demand that we should promote the medical education of the people.

AN OPERATION FOR THE RELIEF OF AN INCARCERATED IRIS.

By GEORGE HUSTON BELL, M.D.,
NEW YORK,
FORMERLY HOUSE SURGEON NEW YORK EYE AND EAR INFIRMARY.

Realizing the number of failures and the bad results that very frequently accompany the operations which are done for the relief of the incarcerated iris, I desire to bring to the notice of the ophthalmic surgeon an operation which, so far, I have never seen fail. It is not recommended, nor can it be employed, in recent injuries which are seen in the first forty-eight hours. It can be used only in what one might call "an old case of incarceration" which has had for its duration four to six days, or longer, and in which the original wound in the cornea has completely healed, leaving the iris jammed between its internal lips. When the nutrition of the cornea has been re-established, it is then that this operation is indicated, and not before. In this class of cases I submit this operation for consideration and approval. As to whether or not a surgeon wishes to operate, after the lapse of several days or more, upon an eye of this kind, must be decided by himself, based solely upon his clinical experience, as there is no hard-and-fast rule laid down by the textbooks on ophthalmology, although Fuchs claims that an incarceration may afterward give rise to increase of tension, to inflammation, and even to sympathetic disease of the other eye. Such deplorable symptoms are not rare, and several times came under my immediate observation while a house surgeon at the New York Eye and Ear Infirmary.

As to the operation, it can generally be done much more satisfactorily, as a rule, under local anæsthesia, although ether is preferred for children under ten years of age. The great principle involved in this operation is the cutting loose of the iris from its attachment to the posterior surface of the cornea, with one sweep of the Von Graefe cataract knife. The technique of the operation is as follows: After the eye has been made as aseptic as possible, either with solution of boric acid or 1 : 5,000 mercuric chloride, the curved linear incision is made with the Graefe knife after the manner employed in doing anterior sclerotomies. Not always cutting upward, not always cutting downward, but sometimes to one side, sometimes to the other, as the case may be, the surgeon using his best judgment, depending entirely upon the situation and the extent of the incarceration, the Graefe knife is entered one-half to one millimetre outside the margin of the cornea, and the blade of the knife is passed into the anterior chamber between the incarceration and the centre of the pupil. The counter-puncture is made the same distance behind the limbus if possible; then the operator cuts from within outward, through the incarceration, on out through the sclera and conjunctiva. It is not necessary for the counter-puncture to be directly opposite the point of entrance of the knife as it is in anterior sclerotomies or cataract extractions. The great object is to make as small a section as possible, and after one gets the point of the knife by the incarceration, one makes the counter-puncture at once, thereby reducing the size of the section to the minimum, for obvious reasons, having always in mind the conjunctival flap. Now the operator turns this flap over the cornea, so that the wound may be exposed to view; then the iris forceps is introduced into the anterior chamber and the iris is caught, drawn out, and excised with the scissors. The columns of the coloboma are then replaced by means of irrigation with a sterilized decinormal salt solution through a bulb syringe, which little device is generally very effective and without any bad results to the lens. Of course, when necessary we resort to the spatula to help us out of the difficulty of freeing the pillars of the coloboma. Too much stress cannot be laid upon this point. The flap of the conjunctiva is then returned to position and the wound is sealed by stroking it with the spatula; one drop of a sixteen-grain solution of atropine is instilled, and both eyes are bandaged for twenty-four hours.

My reasons and plea for the conjunctival flap are as follows: (1) Fuchs claims that scleral wounds are less liable to become infected than those of the cornea, because of the slighter tendency that the sclera exhibits toward purulent inflammation, which is certainly worthy of consideration. (2) Another great advantage, which must not be overlooked, is that the wound heals a great deal faster, thereby causing a quicker restoration of the anterior chamber, which, after all, is the desideratum. (3) The astigmatism is not nearly so great.

This operation has been done successfully a number of times, Dr. Peter A. Callan having performed it frequently at the New York Eye and Ear Infirmary, and always with excellent results. Dr. N. D. McDowell, my successor as house surgeon, as well as myself, has had satisfactory experiences with such cases.

54 East Twenty-fifth Street

Buboes, when suppurating, may be opened painlessly by first injecting beneath the skin a three-per-cent. solution of beta-eucaine. After evacuation a five-per-cent. solution is poured into the wound, and after a few minutes curetting may be performed lightly without pain. One drachm of solution may be thus used with safety. To obviate the prick of the hypodermic needle in very sensitive subjects, first spray with ethyl chloride.—Dalton, *Therapist*, December 15, 1899.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, February 24, 1900.

THE SIGNIFICANCE OF BOVINE TUBERCULOSIS.

IN order to determine this matter in an adequate manner Dr. George Adami, of Montreal, says that the following three main questions have to be asked and answered: (1) Is tuberculosis in cattle a source of danger to other cattle so as seriously to affect their well-being and to be a source of loss to their owners? (2) If infectious from animal to animal, is it infectious from animal to man, and thereby a grave source of danger to the human race? (3) If infectious from animal to man, what are the commonest modes of infection, and, as a sequel to this, how are we to diminish the danger?

The first question Dr. Adami answers with an unqualified affirmative, and gives a mass of statistics collected from different parts of the world in support of his contention. To the second and most important question, while accepting an affirmative as the correct answer, Dr. Adami points out that the amount of reliable evidence of direct transmission of tuberculosis from cattle to man is singularly slight. After drawing attention to the fact that experiments undertaken with the view of proving or disproving this theory have been attended with more or less negative results, Dr. Adami says we are forced, therefore, to fall back upon evidence of another type, and presents the case thus: "Do the bacilli gained from the human and bovine species possess a morphological and cultural identity? They do not. The bovine grow more freely in the ordinary glycerinated media; they are, I find, of greater relative breadth, while again pathogenetically they exhibit different degrees of virulence, and this when inoculated not only into cattle, but into guinea-pigs and the small animals of the laboratory. . . . So far, however, bacilli having all the morphological and cultural characteristics of the bovine 'race' have not been isolated from the human organism, nor do I know that, so far, by placing protected human bacilli in the abdominal cavity of the cow these have assumed the bovine characters. It is in this last experiment, I believe, that the solution of the question is to be found. For if we can show that under favorable conditions the human bacillus can become highly pathogenetic for cattle, the converse would also seem to hold, that there are conditions under which bovine tubercle bacilli can be pathogenetic for man." Dr. Adami concludes that failing experimental and bacteriological evidence of bovine and human tuberculosis, the casuistic evidence while not absolutely convincing is strongly in favor of the view that tuberculosis can be conveyed through the milk of animals extensively diseased.

With regard to the more frequent modes of infection Dr. Adami dismisses rapidly the infectiousness of meat, and goes on to say that with milk the problem presents several difficulties. With the finding of the British Royal commission, that only when the udder is diseased does the milk become infectious, he is not in agreement, being convinced that it is founded on imperfect knowledge, and states that he cannot but come to the somewhat unsatisfactory conclusion that whereas, in the first place, the milk of animals not suffering from udder tuberculosis may contain bacilli, nevertheless such milk is not of high infective power, and that therefore the frequency with which the bacteriologist may by inoculation into the very susceptible guinea-pig find the milk to be infectious is not absolute indication of its danger when employed as a food for man. Only when there is recognizable udder tuberculosis, and active tubercle bacilli are discharged into the milk in enormous numbers in consequence of ulcerative changes occurring in the tubercles, is there real danger. For practical purposes Dr. Adami agrees with Nocard that as regards the milk supply local tuberculosis of the udder is what has to be most especially guarded against, and this not because the evidence at our disposal affords absolute proof of the transmission of tuberculosis from cattle to man, but because the trend of evidence is all in that direction. On the whole, therefore, Dr. Adami is in accord with the chief authorities on bovine tuberculosis with regard to the means of transmitting the disease to man, that the danger from infection from meat is so slight as not to be worth considering; that the principal source of danger is from infected milk, and that only milk procured from cows with diseased udders is to be greatly feared. The question as to what measures should be taken to guarantee a milk supply free from infection has been so fully dealt with in former numbers of the MEDICAL RECORD that further discussion of these points would be superfluous.

It is, however, satisfactory to observe that at the meeting of the Medical Society of the County of New York the question of a pure milk supply was treated at length, and the president of the society was requested to appoint a special committee to consider the possibility of a commission to improve the milk supply of New York.

THE DANGERS OF WATER GAS.

THE substitution of water gas for lighting purposes in the place of coal gas, which has been carried out in many American cities, has been a fruitful cause of numerous fatal cases of asphyxiation. Coal gas is comparatively harmless, containing as it does but from three to twelve per cent. of carbon monoxide, more often the former quantity than the latter. On the other hand, water gas has in its composition seldom less than twenty-five per cent. of carbon monoxide, and not infrequently as much as thirty per cent. and over. Water gas has found favor with the municipalities of a number of American towns for the reasons that it gives a brighter illuminating-power than coal gas, and because it is better adapted for an emergency; that is to say, it can be manufactured more quickly. But although it has these substantial advantages on its side, it is notwithstanding a constant menace to the public health. The danger of carburetted water gas lies in the fact that it contains so large a quantity of carbon monoxide that its inhalation by human beings is always attended by serious consequences to life. Dr. Haldane, one of the British departmental committee appointed to inquire into the manufacture and use of water and other gases containing a large proportion of carbon monoxide, pointed out that in the case of Boston, where ninety per cent. of the gas is water gas, about one in every three hundred deaths is due to accidental poisoning, and the committee resolved that they would not allow in Great Britain more than twelve per cent. of carbonic monoxide in illuminating-gas.

However, no such permissive regulations are likely to be put into force in this country. The American is ever somewhat careless of risks, provided that his comfort and convenience are considered; so that the crux of the problem here is how to treat in the most successful manner those who are unfortunate enough to inhale a sufficient quantity of the gas to become dangerously asphyxiated. Working along these lines, experiments have recently been conducted under the direction of Dr. N. Wiley Thomas, at the physiological laboratory of the University of Pennsylvania, with the object of demonstrating the most effective methods of resuscitating animals poisoned or rather asphyxiated by inhalations of common illuminating-gas. The gas used in the experiments was the ordinary illuminating-gas of Philadelphia, which is composed of hydrogen 26.25; marsh gas, 28.91; carbon monoxide, 27.12; illuminants, 15.80; carbonic acid, trace; oxygen, trace; nitrogen, 1.92. Dr. Darrah's theory of the action of the gas—with which the writer on the subject in Allbutt's "System of Medicine" agrees—is that the asphyxia is due to the fact that the carbon monoxide in the gas forms a stable compound with the hæmoglobin, thus preventing the hæmoglobin from carrying oxygen to the tissues. Dr. Darrah goes on to say that the compound itself has only a slight irritating effect. When animals breathe pure oxygen and small amounts of carbon monoxide, the carbon monoxide is taken up by the hæmoglobin in preference to the oxygen, and forms a compound that cannot be displaced with oxygen. The condition produced in the animals after inhalations of the illuminating-gas resembled in most respects those of individuals asphyxiated by identical means, as dizziness, tottering, and inability to walk. Later in the condition there was low temperature, with rapid, feeble pulse. Respiration was increased in frequency and depth. The remedies first used to relieve this collapse were stimulants such as strychnine, brandy, glonoin, digitalis, followed by inhalations of pure oxygen, electricity, and artificial respiration, but with few favorable results if the condition had been profound. Nor did doses of hydrogen dioxide varying from 10 c.c. to 60 c.c. afford any but negative results. Hydrogen dioxide was next injected intravenously in both small and large doses. The former were without effect, and the latter caused oxidation of the blood with formation of gas in the blood-vessels, causing instant death. Injections of saline solutions did practically no good. Lastly, resort was had to transfusion of blood, the blood being drawn from the carotid artery of a healthy normal dog, and allowed to flow into the jugular vein of an animal under the influence of gas. Dr. Darrah reports that the effect of this method of procedure was magical recovery, occurring in most cases instantly; some few dogs showed symptoms for several hours, but eventually recovered. During the transfusion improvement was noticed in the heart action and in breathing with the first few ounces of blood injected.

From the foregoing experiments Dr. Darrah drew the following conclusions: 1. Small quantities of H_2O_2 have no effect. 2. Large quantities of H_2O_2 have an oxidizing action, with death from gas accumulating in the chambers of the heart. 3. Saline solutions are not of much use; some animals rallied but finally died. Life may be somewhat prolonged. 4. Transfusion abolishes almost immediately the poisonous effects of the gas, with no bad effects except in case of septic infection. It is interesting to note that the dogs from which blood was taken recovered in every instance.

Although the results of the experiments at Philadelphia appear to have been wholly successful, yet there are many medical authorities who prefer to put their trust in inhalations of pure oxygen. Dr. Hare holds that the direct transfusion of blood, even from the same species of animal, is futile, as the corpuscles are destroyed and a transient hæmoglobinuria follows. He stated that in some experiments made by himself and Dr. Martin they had found that inhalation of oxygen produced extraordinary results in dogs poisoned with coal gas. However, the fact should be borne in mind that the experiments undertaken by Dr. Darrah were upon animals which had inhaled much more carbon monoxide than would be contained in any description of coal gas.

Dr. Lorrain Smith reported in the London *Lancet*, in the early part of this year, several cases of gas poisoning which occurred in Belfast. He said that the cases brought out for the first time on record the extreme importance of the secondary effects of gas poisoning. One case on analysis showed the pink tint of carbon-monoxide hæmoglobin. On analysis by the carbon method the blood was found to be fifty-seven per cent. saturated. The blood of one child aged four years was very slightly tinted and not more than five per cent. saturated. Since the child was exposed to the same atmosphere as the adult, it is clear that her blood was at one time at least as highly saturated as fifty-seven per cent. The artificial respiration which was applied by the medical attendant sufficed to clear the carbon monoxide out of the blood. The child therefore died from what may be called secondary effects of gas poisoning on the heart and nervous system. In Allbutt's "System of Medicine" the following modes of treatment are laid down: "Immediate removal of the patient from the presence of the gas, and artificial respiration persisted in for hours in order to expel, if possible, the poison from the blood; Laborde's method of rhythmic traction of the tongue; hypodermic infections of strychnine, and the application of the faradic current to the phrenic nerve—but even with these measures venesection and transfusion of blood may also be necessary. Inhalation of oxygen in some cases is also recommended." Dr. Ransome advises Sylvester's method of artificial respiration.

Taking into consideration the peculiarly insidious narcotizing and fatal effects of carbon monoxide, and the presence of it in large quantities in the gas used in so many American towns, the importance to the public of discovering a really effective means of resuscitating individuals who have fallen under its influence is one that can hardly be overestimated. Experiments such as have been prosecuted at Philadelphia will go far to elucidate these moot points, and if it can be plainly shown that transfusion of blood is the best method to revitalize the almost extinct spark of life in cases of deep asphyxiation, a great boon will have been conferred on that portion of the human race who live in the big cities.

DIETARY STUDIES OF NEGROES.

Dr. Frissell and Miss Isabel Bevier have in connection with the United States Department of Agriculture contributed a series of dietary studies of negroes living in Eastern Virginia. The studies made in 1897 were conducted by Dr. Frissell, and the investigations on the same lines in 1898 by Miss Isabel Bevier. The mode of life and the quality and quantity of the food of the colored race in the United States is a subject that has received but little attention. Some statistics were collected a few years ago with regard to the food consumption of negroes residing near Tuskegee, Ala. These investigations showed that where negro families had profited by the opportunities for education provided at Tuskegee Institute, their methods of living had undergone a considerable change, approaching more closely to those of an ordinary American family. Other families who had not come under such influence might be regarded in the matter of diet as representative of the uneducated negro type.

The results of the studies in Virginia coincided in the main with those arrived at in Alabama. More protein was found in the dietaries of negro families in Virginia than the average amount consumed by white persons in fairly prosperous circumstances, nearly as large as that called for in the tentative American standard—namely, 125 gm. per man daily. This fact, however, is explained by the proximity of salt water to the district in which the investigations were conducted in Virginia, which made fish an important article of diet. The average fuel value of the food consumed per day by the negro families both in Alabama and Virginia is as large or larger than that found in dietary studies made among white families. The average fuel value found in nineteen studies in Virginia was 3,745 calories; that found in twenty studies in Alabama, 3,270; the average of ten white families in New England and New York, 3,515; while the tentative standard for a man at moderate work calls for 3,500 calories per day. Perhaps the most noteworthy feature revealed in connection with these studies was the small cost of the food. For eleven cents the families in Virginia obtained food materials furnishing more protein and more energy than were obtained for twenty-eight cents by the families of professional men in comfortable circumstances, and for nineteen cents by families of well-paid mechanics. It would appear from a consideration of the dietary studies made in Alabama and Virginia among negro families that the character of the food consumed by them is coarser and less appetizing than would be tolerated by an ordinary white family. "Hog and hominy" forms the staple of their diet. Scarcely any meat besides pork is eaten, but where obtainable fish is a favorite article of food, while at certain seasons frogs, turtles, and even snakes are eaten by some families. The cooking of the negroes is primitive to a degree, and their drinking-water is, as a rule, stagnant and brackish, often muddy. The fact, however, stands out prominently that notwithstanding the agricultural negro's careless, unhygienic methods of living, he is able to do hard manual labor and enjoys almost if not quite as good health as his white brother placed in like circumstances.

TYPHOID FEVER IN PHILADELPHIA.

While the authorities are deliberating upon the best means of providing a pure supply of water, the people of Philadelphia are again threatened with an epidemic of typhoid fever. The drinking-water in that city has for some time past been filthy and most unattractive for either bathing or drinking, but a short time ago a number of boys in a mischievous spirit interfered with an intercepting sewer, as a result of which sewage was made to overflow into the Schuylkill at a point not remote from a pumping-station. The statistics tell the rest of the story more eloquently than could any description. For the week ending January 20th there were reported to the Philadelphia bureau of health thirty-five cases of typhoid and eight deaths; for the week ending January 27th, forty-four cases and nine deaths; for that ending February 3d, thirty-nine cases and six deaths; for that ending February 10th, fifty-six cases and six deaths; and for that ending February 17th, seventy-six cases and fourteen deaths. For this last week there are also tabulated thirteen deaths from "inflammation of the stomach and bowels." The whole number of deaths for the city during the week was five hundred and three—thirty-four more than for the corresponding week of last year. As already indicated, the city of Philadelphia has under consideration the report of a commission of experts on water purification, which it has adopted, and for putting into execution the recommendations of which it has voted the making of a loan of many millions of dollars; but with conventions to look after, vacant senatorships to fill, patronage to solicit and dispense, franchises to give away, ballot-boxes to stuff, election returns to falsify, and other congenial occupations, office-holders and politicians may see no need of haste in providing a better water supply—and the people will get what they deserve from those they selected to act as their representatives.

News of the Week.

A New Anti-Tuberculosis Serum.—The *Sei-i-Kwai Medical Journal* announces a discovery which will doubtless have most important consequences if the author's hopes are realized, in the following terms: "Fleet-Surgeon T. Yabe, of the imperial Japanese navy, who is now studying bacteriology in the Pasteur's Institute, Paris, discovered some method to make human subjects immunity from the tubercular disease with some material which he calls tuberculo-immunitine. We heartily congratulate his success for such great and difficult subject which was considered almost impossible to achieve at among the imminent authorities in Europe and America."

A Suit for the Value of Epidermis.—A young woman recently sued a physician of North Adams, Mass., for damages for having taken more skin from her body for grafting purposes than she claims to have authorized him to take. She had consented to furnish the material for skin-grafting in a case in which that operation was necessary, but after the operation was concluded she claimed that the surgeon had denuded her too much. The judge, however, decided that there had been no specification as to the amount the plaintiff was willing to give, and consequently the defendant was at liberty to take all he needed. The case has been appealed to a higher court.

Heat in South America.—On February 5th, there were two hundred and sixty-seven cases of sunstroke in Buenos Ayres, and one hundred and eighty-seven on the following day, making a total of seven hundred and seventy-five cases in four consecutive days. The number of fatal cases was large. In Montevideo there were also many cases of insolation. The distress in Argentina was increased by a strike of the grave diggers for higher pay, and numbers of dead bodies were left to decompose in the cemeteries above ground. The intense heat destroyed the corn crop.

Contesting Chiropodists.—A suit has been brought by the president of the Academy of Chiropody against members of the Pedic Society for alleged discrimination against him by the society. It is alleged that the two members of the society, who are also the State examiners in chiropody, conduct a school, and favor their own pupils in the examination to the detriment of the academy, the pupils of which are thus not on an equal footing with the other students, and the president of which has no standing in the Pedic Society.

Lepers in New York.—A physician in this city having asserted that there are a hundred lepers, more or less, at large in New York, the president of the board of health is said to have called upon him for his proofs. There are unquestionably lepers in this city under medical treatment, but we doubt whether there are one hundred.

A New Fasting Man is undergoing a self-imposed forty-days' abstinence from food in Mount Vernon, N. Y. He has already passed about thirty-five days without food, as alleged, and is confident of completing his fast without injury.

Possible Closure of a Hospital.—The managers of the Flushing Hospital are said to contemplate closing its doors, because under the present rate of payment made to hospitals for public patients by the city the institution finds itself running heavily in debt. The city allows eighty cents a day for surgical cases and sixty cents for medical cases, and during January the income from this source was only about $200, while the expense of maintaining the hospital was nearly $1,000.

The Famine in India.—A despatch to the *Sun* from Bombay, dated February 7th, says that the famine in India is rapidly becoming worse, and threatens to eclipse the last disaster of this nature, and to outrun the government's resources. Already four million persons are receiving relief, and a steady increase in this number is to be expected. Deaths from starvation are becoming frequent, especially in Rajputana. The advent of famine refugees to Bombay city aggravates a situation that is already serious owing to the prevalence of the plague, smallpox, and other epidemic diseases.

A Board of Health for Havana.—Before leaving Cuba last week, General Ludlow organized the Havana board of health by the appointment of Drs. Emiliano Nuñez, Charles Finlay, Benito Valdez, Carlos Desvernin, Joaquin Jacobsen, and Manuel Delfin. The chief surgeon of the United States troops and the chief sanitary officer of the department will be ex-officio members so long as the military department exists. The mayor of the city will be ex-officio president of the health board. The board will have responsible executive functions, exercised under the provisions of suitable rules and regulations drafted in accordance with modern science and practice. The functions of the board will be exercised subject to the orders of the military governor. Major John G. Davies, the chief sanitary officer of the department, applied for transfer to the Philippines, and has already been ordered to report at New York.

The Louisiana Leper Home.—The board of control of the leper home of Louisiana will at an early date select a site and erect a permanent home for the lepers of the State. The present home is situated at a point rather inconvenient for caring for patients to the best advantage, and it is the intention to select a site for the new buildings nearer New Orleans where every convenience can be obtained, and where scientific observations can be carried on. The funds for the erection of the buildings were appropriated by the State legislature. There are at present thirty-three inmates of the home.

Trouble in the Harlem Hospital.—The commissioner of public charities has suspended two of the physicians of this hospital and reprimanded the female superintendent with threat of dismissal, on account of a quarrel which has been agitating the officials of the institution for some time past.

Smallpox at Bellevue.—An orderly in the erysipelas ward at Bellevue Hospital was recently found to be suffering from smallpox. He was transferred to North Brother Island, and all those with whom he had come in contact were revaccinated. It has not been discovered how he acquired the disease.

State Hospitals Independent of the City.—The New York City authorities have claimed that, under the charter of the city, they have the right to inspect the buildings, boilers, etc., of the Manhattan and the Long Island State hospitals, but this claim has been resisted by the officials of these hospitals. The dispute was referred to Attorney-General Davies at Albany, and he has decided that the city has no jurisdiction.

The Barren Island Nuisance.—The State board of health in its last annual report claims that the garbage-rendering establishment on Barren Island is less of a nuisance than those living in the neighborhood hold it to be. It asserts that "while under certain atmospheric conditions the odors from this plant can be detected at the places from which these complaints are sent, it is so modified by the appliances before mentioned that it is scarcely noticeable, and is not in any way injurious or detrimental to health or comfort."

Yellow Fever has reappeared in Havana at an earlier period than usual, the city being ordinarily comparatively free from the disease until well into the spring. On February 14th there were eight cases under treatment. The presence of the disease is attributed to the exceptionally warm weather and to the presence of so many unacclimated Spaniards and Americans.

Capital Punishment in New Jersey.—Two bills have recently been introduced into the New Jersey legislature dealing with capital punishment. The first provides that in murder trials if a jury return a verdict of murder in the first degree, accompanying the finding with the phrase "without capital punishment," the defendant's punishment shall be imprisonment for life. The second substitutes the electric chair for the gallows in the execution of the death sentence.

The Stickler Memorial Library.—The plans have been accepted for the library building at Orange, N. J., which the parents of the late Dr. J. W. Stickler are to erect in memory of their son. The medical library of the deceased physician is to be placed in a room in the new library building for the use of medical students, and his entire laboratory apparatus has been given by his widow to the Orange Memorial Hospital. Mr. and Mrs. Stickler have also given $40,000 to the Orange Young Men's Christian Association for the erection of a new building, to be known as Stickler Hall, and which will also be a memorial to Dr. Stickler, who was the first president of the association.

Dr. Jameson, who led the Transvaal raid a few years ago, for which he was imprisoned in England, is in Ladysmith, and is reported to be ill of a fever, the nature of which is not stated.

The Hospital Ship "Missouri" arrived in San Francisco from Manila on February 16th, with two hundred and sixty-nine wounded and invalided soldiers from the Philippines. Eighteen died during the voyage.

The Inoculation of Malaria by the Mosquito.—In the article with this title by Dr. Irving Phillips Lyon, which appeared in the MEDICAL RECORD for February 17th, the name of the tick which carries the germ of Texas fever should have been Boöphilus bovis, instead of Pyrosoma bigeminum, which is the name of the organism that the tick carries.

The Sale of Drugs in Department Stores.—A bill to prohibit the sale of drugs in department stores in this city has been advanced to the third reading in the State assembly. It was opposed on the ground that it was too radical, as under its provisions a department store could not even sell cough drops, and the constitutionality of the measure was also called in question. The bill was advanced to the third reading, however, by a vote of sixty-five to forty.

The Influenza still afflicts Europe, and the cable brings the names of many prominent personages among the hundreds of thousands who are suffering from it. In Paris President Loubet and Sarah Bernhardt, and in Berlin Ambassador White, the Empress Augusta Victoria and two of her sons, and the burgomaster have been among those attacked. General Krautwurst, a surgeon in the German army, has died of the disease. In this city the number of cases diagnosed as influenza and of respiratory affections which may be attributed in part to this disease has been steadily increasing during the past two weeks, and doubtless will increase still more during the weeks yet to come.

Hospital Corps for South Africa.—Between fifty and sixty men constituting the "Irish-American Hospital Corps" recently sailed from this port for Havre on the way to Pretoria, where they will offer their services to the Boers. They were not recognized by the Red Cross Society until each man had taken an oath that he was over twenty-one years old, that no women were dependent upon him for their support, that he was working for no compensation, and that he was going within the Boer lines not as an ally, but merely to give aid and comfort to the injured and sick. There are six surgeons, six assistants, nurses, litter carriers, and other attendants. The surgeons are Drs. J. R. McNamara, Herbert McAuley, James J. Slattery, R. L. Long, A. F. Corney, and J. B. Aderholt. They have six assistants. The litter carriers and other attachés are under the command of Capt. Patrick O'Connor. The men will wear a khaki uniform with the red cross on the sleeves and on the hat. Their outfit consists of medical supplies, surgical implements, surgical dressings, tents, and emergency kits for field work. A movement has been started by English-born Americans to organize a similar hospital corps to care for the British sick and wounded in South Africa. It is reported from Lorenzo Marques that the Portuguese authorities have seized two large cases of saddles forming part of the baggage of the Russo-Dutch Red Cross contingent that arrived at that port a short time ago, the claim being made that saddles are contraband of war.

The Gallaudet Home for Deaf-Mutes, near New Hamburg, N. Y., was totally destroyed by fire on last Sunday night. The twenty-six inmates, some of whom are blind and others very feeble, who were all in bed, were safely carried out of the building.

The Plague.—Up to February 17th there have been forty-two cases of plague, with thirty-two deaths, in Manila, about twenty of these being among Chinamen. A hundred inspectors, thirty of whom are Chinamen, are employed in enforcing the sanitary regulations and ferreting out the cases of the disease, which are often concealed by the friends of the sufferers.—In Honolulu four new cases of the plague were reported subsequent to the destruction of the Oriental quarter of the city, but advices dated February 9th say that no new cases had developed during the past four days, and the health officials had granted permission for churches, schools, and places of amusement to reopen. War has been declared on rodents, a bounty having been offered for rats dead or alive, and every householder having been supplied with poison for use on his premises.—A despatch from Rio de Janeiro states that the Brazilian government announces that Argentine and Portuguese ports are free from the plague.—The St. Petersburg Institute of Experimental Medicine has established a laboratory for the study of plague and for the manufacture of plague serum at Cronstadt. The laboratory is surrounded on all sides by water. There are stalls for twelve horses, and apartments for the medical officers and their assistants, with a lazaretto in case infection occurs among any of the staff.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending February 17, 1900. Medical Inspector H. H. Simons commissioned medical inspector from September 24, 1899. Medical Inspector H. Wells commissioned medical inspector from January 15, 1900. Medical Inspector M. H. Simons detached from the naval recruiting rendezvous, New Orleans, La., and ordered to the *Philadelphia* as fleet surgeon. Medical Inspector T. H. Streets detached from the *Philadelphia* as fleet surgeon on reporting of relief, and ordered to the New York navy yard. Passed Assistant Surgeon J. C. Rosenbleuth ordered to the naval recruiting station, New Orleans, La. Surgeon H. M. T. Harris commissioned surgeon from October 21, 1899. Assistant Surgeon Karl Ohensorg appointed from January 27, 1900. Passed Assistant Surgeon G. L. Barber ordered to the *Kearsarge* February 20, 1900. Assistant Surgeon D. G. Beebe detached from the *Petrel* and ordered to Port Isabella.

Alleged Cancer Cures.—California is prolific in newspaper cures for tuberculosis, alcoholism, cancer, and other ills. The latest is a telegraphic report of the cure of a cancer of the face of twenty-five years' standing by means of *x*-rays. A "cancer" of that age might be regarded as obstinate, but could hardly be denominated malignant. The reporter of the case cautiously remarks that it is uncertain what effect the Roentgen rays may have on carcinoma of the internal organs.

Mr. William Adams, a well-known English orthopedic surgeon, has recently died. He was consulting surgeon to the National Hospital for the Paralyzed and Epileptic. He was known especially for his work in operations for the relief of ankylosis of the hip.

The Late Dr. William A. Hammond.—The New York Neurological Society desires to record its regret at the death of Dr. William A. Hammond, one of the founders of this society and for many years one of its most active and distinguished members. Dr. Hammond was one of the pioneers of neurology in this country. His work was always suggestive and most lucidly presented, and it was often original and of permanent value. It has indissolubly linked his name with the history and growth of neurological science. It was before this society that many of his papers were presented. We record our appreciation of his work as well as of his brilliant mental gifts. These were most helpful to this society in its beginnings, and led to enduring results in the advancement of clinical neurology and psychiatry and the development of neurology in America.—CHARLES L. DANA, LANDON CARTER GRAY, GEORGE W. JACOBY.

Obituary Notes.—DR. WOOLSEY HOPKINS, of this city, died on February 15th from pneumonia, at the age of thirty-two years. He was born in Alexandria, Va., and was graduated from the College of Physicians and Surgeons, New York, in the class of 1890. He was assistant surgeon to the Manhattan Eye and Ear Hospital, and was a member of the American Laryngological, Rhinological, and Otological Society. A widow and two children survive him.

DR. GUSTAVE MOZART STOECKEL, of this city, died at his country home in Norfolk, Conn., on February 15th, at the age of fifty-one years. He was a graduate of the College of Physicians and Surgeons in the class of 1874.

DR. WILLIAM H. HASTINGS died at his home in Boston on February 16th, at the age of sixty years. He was a graduate of the Harvard Medical School in the class of 1868. In 1869 he became district physician of the Boston Dispensary, and was appointed superintendent in 1876, which place he occupied continuously from then up to the date of his death.

Dr. De Witt C. Green, of Florence, Ala., died in consequence of a fall from the roof of his house on February 14th. He was a graduate of the Jefferson Medical College in 1882.

Dr. John D. Hillis died in West Haven, Conn., on February 15th, at the age of forty-five years. He was born in Poughkeepsie, N. Y., and was graduated in medicine from a school in Cincinnati. He practised for a time there and later in Chicago, but afterward engaged in mercantile pursuits. A widow survives him.

Dr. Horace R. Allen, of Chicago, died in consequence of a surgical operation at the Presbyterian Hospital in that city on February 13th. He was a graduate of the medical department of the Western Reserve University in the class of 1857.

Dr. Edward Lorenzo Holmes, of Chicago, died on February 12th, of pneumonia, at the age of seventy-two years. He was born in Dedham, Mass., and was graduated from the Harvard Medical School in the class of 1854. He settled in Chicago soon after graduation, and there devoted himself chiefly to the study of disease of the eye and ear. He was for many years professor of ophthalmology and otology in the Rush Medical College, and was one of the founders of the Illinois Charitable Eye and Ear Infirmary. He was a member of the American Ophthalmological Society and of the American Otological Society, and was a frequent contributor to the literature of diseases of the eye and ear.

Dr. Samuel R. Forman died at his home in Jersey City, on February 19th, of Bright's disease, at the age of sixty-four years. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1857.

Dr. R. A. Kennedy died at Shamokin, Pa., on February 9th, in an apoplectic attack, at the age of forty-four years. He was a graduate of Bucknell and of the medical department of the University of Pennsylvania.

Dr. Gerald J. M. McMurray died at Philadelphia on February 10th, of meningitis, at the age of thirty years. He was graduated from Jefferson Medical College in 1894.

Dr. Charles B. Kennedy died of heart failure at Hollidaysburg, Pa. He was a graduate of Bellevue Hospital Medical College.

Dr. William W. Lamb died at Philadelphia on February 15th, at the age of fifty-nine years. He was a graduate of the Long Island Medical College. He was an assistant surgeon in the Eighth New Jersey volunteer regiment during the Civil War, from 1872 to 1885 an inspector of drugs, from 1872 to 1890, surgeon to the Third Regiment Pennsylvania National Guard, from 1890 to 1892 assistant surgeon to Battery A, and from 1871 a police surgeon. He was further surgeon to the Methodist Home for the Aged and to the Methodist Orphanage.

Meddlesome Probing is condemned in military surgery by Dr. Senn in his "War Correspondence," the old-fashioned probe having been entirely superseded by dissection and the use of the *x*-rays.

Progress of Medical Science.

Medical News, February 17, 1900.

Report of Bacteriological Investigations upon Yellow Fever.—Aristides Agramonte gives the results of experiments in which he injected serum taken from convalescents from uncomplicated yellow fever. The serum is perfectly innocuous; it is more readily absorbed than the equine serum. It has never produced any cutaneous manifestation, and within twenty-four hours every sign of the injection has disappeared except at the point of puncture, where a minute red spot may be visible. No case is injected which is seen after the fourth day of the invasion. The disease has been distinctly modified in every instance. In these experimental injections two facts have been emphasized: (1) the absence of hemorrhagic tendency; (2) the rapidity with which patients who received the serum went through the period of convalescence; the fever having once left them, their reparative functions were quickly started, and they were ready to return to business in an unusually short period of time.

An Improved Operation for Acute Appendicitis or for Quiescent Cases with Complications.—Robert F. Weir in this method increases the intermuscular space of McBurney. He tears off with the finger-tips, or with the end of blunt scissors, the already denuded fascia of the external oblique muscle from the sheath of the rectus quite up to the median line, where it is held retracted by an assistant. The anterior sheath of the rectus is now divided transversely in a line continuous with the opening made in the peritoneum by the original muscle-separation operation. The outer edge of the external rectus is then lifted up and carried by a retractor to the median line. The epigastric vessels should be divided and ligatured. The posterior sheath of the rectus and the peritoneum should be cut in a manner similar to the outer sheath. When blunt retractors are now passed into the peritoneal cavity and the abdominal wall is put on the stretch, there is a very superior exposure of the whole pelvis and of the right iliac fossa.

Two Cases of Rupture of the Right Lobe of the Liver; Laparotomy, Recovery.—H. Beeckman Delatour says that the question of when to operate in these cases is the all-important one and must be decided for each case individually. In the first of these two cases, had operation been at once resorted to, probably a fatal issue would have resulted, while in the second case unavoidable delay nearly cost the patient's life.

A Consideration of Acute Inflammatory Rheumatism.—W. H. Neilson believes that inflammatory rheumatism is an infectious disease; that its natural history points to this, its complications point to it, and the treatment found so effective proclaims it. He approves of the use of salicylic acid and its compounds.

The Bubonic Plague.—Edwin Klebs declares that the bacillus pestis bubonicæ is undoubtedly the cause of bubonic plague. The first step in combating the spread of the plague must be by general hygienic measures. The demonstrated cases should be at once isolated in a plague hospital.

A Case of Post-Epileptic Amnesia.—David Trumbull Marshall reports this case, in which the amnesic period was ten days. There was great difficulty in obtaining a history of epilepsy, since the family did not wish the matrimonial prospects of the patient blighted.

Journal of the American Medical Ass'n, Feb. 17, 1900.

The Hockey-Stick Incision.—Willy Meyer describes this incision, useful in certain complicated cases of appendicitis. He says that its chief advantage is that it enables the operator to respect the fibres of the external oblique muscle, and that, if properly lengthened at its lower angle, it gives sufficient access to the small pelvis and its contents for whatever work may be necessary, at least as far as the adnexa of the right side are concerned. The author calls it the "hockey-stick" incision on account of its shape. In most cases the incision commences at a spot about one-half inch above and midway between McBurney's point and the anterior superior spine, and ends about one-half to three-quarters of an inch from Poupart's ligament. Meyer has used this incision in ten cases of appendicitis, gangrenous, perforative, or complicated with tubal or ovarian affections, and recommends it as a typical mode of entering the abdominal cavity in such cases, as by it extensive work can be done within the small pelvis without necessitating an additional median incision.

Have We in Nature a Basis for a Science and Art in Medicine ?—H. J. Herrick says it is the purpose of this paper to show that the conditions with which the physician deals have such uniformity of phenomena and facts that the subject may be properly termed a science, and that such conclusions may be reached and practical results attained, as to be unquestioned by any intelligent inquirer, and that when those principles are applied to practical use for the curing of disease, it may appropriately be styled an art.

Why the Negro Does Not Suffer from Trachoma.—Warwick W. Cowgill says that this disease is common only among the poorer classes of whites in the country districts. Between this class and the negro there is a wide gulf fixed. Assuming therefore, as the author does, that the disease is contagious, the conclusion is reached that the negro owes his immunity to his lack of contact with the source of contagion.

Bilharzia Hæmatobia.—Edwin Walker says that the authors who have described this parasite all supposed that Africa was its only habitat. But one other case has been reported in this country, the patient being a resident of Sparta, Ill. In the case reported by Walker great care was taken to avoid error; the parasite was found in the specimen of urine passed in sterile vessels, as well as that drawn by catheter.

Mucocele in the New-Born.—Clark W. Hawley reports six cases of this disease in his practice, from observation of which he has reached the following conclusions: 1. The disease is a rare one. 2. The indications are to establish drainage into the eye if it is not possible to cause flow into the nose. 3. The tumor should be opened by a very small incision. 4. An anæsthetic should be given and probing done.

The Maddox Rod or Phorometer ?—Alvin A. Hubbell gives results of his own experience with these two forms of test, and says that in view of the fact that by the rod test there is introduced no extraneous impulse to muscular contraction, and as its findings are in the great majority of cases equal to or in excess of the phorometer, he believes the rod to be the more precise and trustworthy guide in daily practice.

Corneal Corpuscular Activity.—In his discussion of this subject Joseph E. Willetts says that the phenomenon consists of bright moving bodies filling the field of vision. He adds that all the evidence is in favor of these bright bodies being the amœboid leucocytes circulating through the lymph canals of the cornea.

Railway Hygiene and Emergency Equipment.—W. W. Grant says that the present methods of ventilating cars and of cleaning their furniture are entirely inadequate. He suggests many radical improvements, including the equipment of every train with a hand litter for the removal of the sick.

Operative Treatment of Chronic Glaucoma.—Alexander W. Stirling discusses the usual operations for this disease, viz.: iridectomy, sclerotomy, and sclero-iritomy. As to the relative advantages of myotics or operation he thinks it impossible to speak dogmatically.

Eviscero-Neurotomy.—J. G. Huizing describes a new method for evisceration of the eyeball, and claims for it all the advantages of the Mules operation, as well as those of enucleation, without their disadvantages.

Convergent Strabismus.—William B. Meany reports this case of total apparent strabismus—convergent—of 62°, in order to demonstrate the method used for this individual case by Professor Landolt in his clinic.

Eosinophilia in Dermatitis Herpetiformis (Duhring).—Mark A. Brown and George P. Dale report a case of this disease in which a clinical examination of the blood changes showed a large percentage of eosinophilia (at one time 44.3 per cent.).

The Bubonic Plague.—Edmond Souchon gives some points of special interest to sanitarians regarding this disease, which he has gathered from the writings of Kitasato, Nakagawa, Yersin, Wyman, and Manson.

Treatment of Septic Conditions in Children.—By Edwin Rosenthal. See MEDICAL RECORD, vol. lvi., page 27.

New York Medical Journal, February 17, 1900.

The Importance, both Medico-Legal and Clinical, of the Early Recognition of Certain Organic Affections of the Nervous System, Including Paresis.—J. Leonard Corning discusses the early symptoms of locomotor ataxia, multiple sclerosis, paralysis agitans, and general paresis. All these maladies play a considerable part in the litigation of to-day to determine the presence or absence of insanity. He calls attention to the care necessary in studying the symptoms of prisoners in order to arrive at a proper diagnosis, and shows how juries are often influenced by the lay idea that organic disease of the nervous system necessarily entails insanity.

A Plea for the More Extended Use of Antitoxin for Immunizing Purposes in Diphtheria.—From statistical tables compiled from New York City Health Reports, J. S. Billings claims that the increased number of cases of diphtheria in the city for 1899 was due in part (in the author's view) to a neglect of immunization by antitoxin. He believes that 300 units should be used in children and 500 units in adults.

Four Cases of Diabetes Mellitus of Apparent Bacterial Origin, and their Successful Treatment.—J. P. Sheridan states his belief in the bacterial origin of this disease, though he gives no proofs to sustain his position. He finds the ideal remedy for the malady in a combination of the bromides of gold and arsenic.

Overstudy.—L. M. Yale is sceptical as to the fact of overstudy being the cause of physical ailments, but believes that physical ailments underlie difficulty in school work. The physician should never accept "overstudy" as a cause for deranged health until he has carefully sought for and failed to find a physical reason.

Digitalis and Aconite; their Physiological and Therapeutic Value.—F. O. Hawley makes a study of the peculiarities of these drugs and condemns the loose methods of assay so frequently practised. To the resulting unreliable preparations we owe much of the uncertain effects so often seen in administration.

The Therapeutic Value of Alcoholic Stimulants.—F. A. Castle maintains that it is the volatile ethers which give to wines and spirits their chief therapeutic value.

The General Treatment of Phthisis Pulmonalis.—G. A. Evans discusses the general therapeutics of the disease, and gives tables referring to diet and mode of living.

Skin Manifestations of Influenza Observed in the Present Epidemic.—J. E. Herman has seen eruptions resembling respectively measles, scarlatina, and herpes.

Studies on Internal Antisepsis.—By E. Klebs. A continued article.

Philadelphia Medical Journal, February 17, 1900.

The Pleural Friction Sound.—Albert Abrams describes several manœuvres of value in eliciting this sound. (1) Respiration is suspended, and then the arm on the affected side is raised while in extension, the suspected area being auscultated in the mean while. (2) The patient lies on the affected side for a minute or two and then rises suddenly, suspending respiration. The affected area is now auscultated while the patient takes a deep breath. (3) Pressure in an intercostal space with the buttoned rod of the phonendoscope screwed to a piece of tin, which is fitted over the hard-rubber bell of the stethoscope. The phonendoscope itself cannot well be used, for when pressure is exerted with the buttoned rod in the intercostal space the patient's breathing gives rise to adventitious sounds which are confusing.

Gangrenous Stomatitis Treated with Antistreptococcus Serum.—W. C. Cahall reports a case of noma in a child seven years old suffering from typhoid fever. The disease was treated first by cauterization, then by the curette, and finally by an extensive cutting operation, but each time the gangrene reappeared. Then an injection of 10 c.c. of antistreptococcic serum was made, and within twelve hours a line of demarcation formed, and within twenty-four hours the gangrenous part had disappeared, leaving a healthy-looking wound.

The Earliest Recorded Autopsies in America.—Francis R. Packard says the earliest mention of an autopsy in America is to be found in "An Account of Two Voyages to New England," published in London by John Josselyn in 1674. Four other post-mortem examinations were made in New England during the remainder of the seventeenth century.

An Unusual Case of Molluscum Fibrosum.—Daniel H. Williams report the removal of a tumor of this character weighing twelve and one-half pounds and measuring fifteen by eighteen and one-half inches.

The State Care of Consumptives.—Charles E. Nammack enters a plea for the fresh-air treatment of tuberculosis and for the establishment of State sanatoria for the poor.

Position Symptoms in Joint Disease.—By Harry M. Sherman. See MEDICAL RECORD, vol. lvi., p. 494.

Boston Medical and Surgical Journal, February 15, 1900.

The Clinical Value of Oliver's Hæmocytometer.—David D. Scannell describes this instrument in detail and extols it as being time-saving and accurate as compared with the Thoma-Zeiss procedure.

A Case of a Man who Swallowed his Suspenders.—Maurice H. Richardson by external œsophagotomy extracted the ingested wearing apparel, and the patient, a previous inmate of an insane asylum, made a good recovery.

A System of Clinical Instruction.—A. H. Wentworth describes the method which he employs for the simultaneous instruction in small sections of a large number of students.

Diffuse Peritonitis from Acute Appendicitis.—J. Coplin Stinson reports a case in a young girl in which operation was followed by recovery.

Medical Press and Circular, Jan. 31 and Feb. 7, 1900.

The Correlation of Sexual Function with Insanity and Crime.—H. Macnaughton-Jones concludes his paper, taking up climacteric insanity, which occurs chiefly in women but also in men. The correlation of insanity and disordered sexual functions arising out of affections of the generative organs is a factor to be taken seriously into consideration. A careful examination should be made when there is suspected a condition of the generative organs which might produce or aggravate the mental affection. Due weight should be given irregularities in investigating criminal acts in women, especially during the menopause, etc. The special dangers of the climacteric period (climacteric mania) must be remembered. Pelvic examination should be made when moroseness, depression, hysteria, hallucinations, unfounded suspicions, and apprehension are leading symptoms. There is greater predisposition to mental disturbances after operations on the generative than other organs. Those previously insane are predisposed to relapse under such operations. Suicidal impulse and crime at the climacteric should be anticipated by operation if gross lesions are detected.

A Rare Form of Ulceration of the Female Urethra.—Richard Dancer Purefoy says the external female genitals furnish some of the best illustrations of chronic syphilitic disease being confounded with malignancy. In a case observed there was upon the inner surface of the left nympha a circular excavation with sharp cut overhanging edges, the base being white cicatricial tissue. The entrance to the vagina was closed by a morbid growth with red nodular surface hanging from an enormously dilated urethra. Dr. West had seen six similar instances—mostly in women giving a history of syphilis or venereal disease. The writer has seen it as an independent affection and also associated with condylomata. The lower wall of the urethra is often like cartilage and the aperture is permanently patulous. Sometimes the urethra will admit one or even two fingers through its whole extent. Strong nitric acid may produce enough contraction to control the urine. This rare affection is similar to, if not identical with, Huguier's lupus hypertrophicus.

A Case of Posterior (Congenital) Luxation of the Shoulder Joint.—G. Burbridge White says posterior luxation is the most unusual form which congenital dislocation of the shoulder assumes. He relates an instance in which, when examined, there was total inability to move the arm or forearm, to pronate or supinate or to flex or extend the hand. The forearm was turned in so that the dorsum of the hand rested on the loin. Treatment consisted in careful massage until motion in the arm independent of that of the scapula took place. When slight active motion was possible, dumbbells and an American elastic exerciser rendered improvement more rapid. After twelve months there was considerable use of the arm possible. The *x*-ray confirmed the diagnosis of luxation of the acromial end of the clavicle and atrophy of the head of the humerus.

Five Cases of Angina Pectoris.—Dr. Salomon reports five similar cases. There were no asthmatical symptoms. In a few weeks the pain began to radiate to the left arm. The pain was often started by slight movements, as in undressing. The duration of the attack was from ten minutes to several hours. Three patients died, and two recovered. Two had had syphilis, one influenza. The writer does not believe that iodides are of benefit in genuine ordinary angina. Patients with coronary angina die; those with neurasthenic angina get better. Iodides along with hygienodietetic treatment must always occupy the first place.

The Dilatations and Diverticula of the Œsophagus.—John Knott divides these rare abnormalities into congenital and acquired, each being arranged, according to Rokitansky, under three heads: (1) The cylindrical or fusiform, in which a great part of the length of the tube is enlarged; (2) the sacciform, in which one or more pouches are found, which involve all the coats of the œsophagus; (3) the hernial, in which the mucous membrane alone expands, and this coat, protruding through the muscular layers, forms diverticula or herniæ. Illustrations are given, and the subject is to be continued.

Some Remarks on the Operative Treatment of Uterine Fibroids.—W. Gow supports the view that, of all radical operations for fibroids, abdominal hysterectomy with subperitoneal treatment of the stump is the best and safest procedure, and that this operation may confidently in the future be looked upon as giving a mortality of not more than one or two per cent. He relates four cases in which single or double pyosalpinx existed, and gives a table of forty-seven patients treated in this way with a mortality of just over two per cent. There were thirty-nine consecutive cases of recovery.

Acute Chorea Treated with Large Doses of Arsenic.—Murrell carried out the treatment recommended by William Murray, but somewhat modified. Instead of giving fifteen drops of liquor arsenicalis three times a day for a week, he gave smaller doses over a longer period, but vomiting was a distressing symptom, and the drug was discontinued. He finds that the duration of the attack is immensely shortened by giving arsenic.

Some Remarks on the Oils of Cajeput and Cubebs and their Use in Inhalation.—Robert J. Lee finds that these oils may be vaporized without difficulty, and as their properties are well understood it is unnecessary to point out the class of cases in which they may be inhaled with benefit.

Ambrose Paré and his Times.—J. Grant Andrews gives an entertaining account of Paré's life.

British Medical Journal, February 10, 1900.

An Undescribed Form of Plague Pneumonia.—W. C. Hossack reports five cases of an indefinite and obscure form of plague, differing in character and general symptoms from the classical form of plague pneumonia in that its onset is not fulminant but insidious, and the symptoms are slight. The most striking characteristic of the disease is the pulse, which presents grave characters quite out of harmony with the brief duration of the illness and the limited amount of lung mischief. Every case the writer has heard of, including the five coming under his immediate notice, have ended quite unexpectedly in death on the fifth to the tenth day. In answer to the probable objection that these cases were not plague at all, but simple broncho-pneumonia, the writer evidences their clear connection with the plague, their occurrence in series with indisputable plague cases, and their apparently inexplicable fatality.

Preventive Inoculation against Bubonic Plague.—A. Lustig and G. Galeotti assert that preventive inoculation is the only means by which this disease may be rationally combated when it has manifested itself in epidemic form. They give the results of experiments on animals by means of a nucleo-proteid which they have succeeded in extracting from the plague bacilli. The authors claim that this product is free from the drawbacks of Haffkine's vaccine, and that its advantages may be summed up as follows: (1) Its efficacy has been proved from the experiments made on various animals; (2) the substance is innocuous in the case of man; (3) if the cultural liquids possess an immunizing power they owe it to the nucleo-proteid which the writers have isolated; (4) the advantages of using an active substance isolated and pure instead of cultures which contain it mixed with heterogeneous elements are evident.

A Case of Malignant Malarial Fever with Cerebral Symptoms Terminating Fatally, in England.—D. C. Rees reports this case, and says that he has never seen such an enormous number of parasites in the peripheral circulation in any case of malignant malaria. It is noteworthy that the patient was only five days in a malarial country. The writer points out the importance of blood examinations in such a case as this. The patient was unconscious; no reliable history could be obtained; he had practically no pyrexia, no rigors, no sweating; without the blood examination the diagnosis of malaria would hardly have been justifiable.

The Serum Diagnosis of Mediterranean Fever.—T. Zammit says in every case of fever the method of serum reaction should be used in diagnosis. He submits the following facts gathered during the past year: (1) The micrococcus of Bruce can be grown successfully from a culture seven months old; (2) cultures of the micrococcus two years old give a clear serum reaction; (3) the micrococcus does not grow on sea water solidified with agar, not even when the water was taken from a sewage outfall; (4) the micrococcus grows on an agared solution of normal human fæces.

A Case of "Beef Worm" (Dermatobia Noxialis) in the Orbit.—This case is reported by Frederick T. Keyt. He says the "beef worm" is commonly found in British Honduras and Central America, in dogs and cattle, and often in human beings. The natives treat it by applying tobacco leaf over the swelling and occluding the orifice; the worm is narcotized or killed, and its expulsion is easily effected by squeezing. Occasionally it gives rise to serious inflammation of the subcutaneous tissues, demanding liberal incision and free drainage.

Cinnamon in the Treatment of Tropical Diarrhœa.—A. Norris Wilkinson reports good results from the use of cinnamon in teaspoonful doses, mixed with milk to mould it into the shape of a bolus, and chewed night and morning. In all cases ranging from ordinary diarrhœa to severe cases of dysentery the author relies upon this mixture given in conjunction with a mixture of quinine sulphate, potassium bromide, and antifebrin.

Poisoning by Castor-Oil Seeds.—In this case, reported by W. P. Meldrum, the patient, a dock laborer in good health, ate a couple of castor-oil seeds. No medical assistance was sought for three days. There were then incessant purging and vomiting with cold extremities and weak pulse. Under treatment the purging stopped, but the vomiting persisted, and the patient expired from exhaustion.

Some Researches into the Nature and Action of Snake Venom.—In his account of these researches Robert Henry Elliot describes his method of collecting and storing venom, bile, etc.; he gives the standardization of solution and mode of administration, describes the preparation of the animal, with the calculation of dose based on idiosyncrasy, and notes the variations in lethal dose for different animals.

A Case of Vesical Calculus in Sierra Leone.—In this case reported by W. Renner recovery followed lithotomy. The author says the case is of interest from the fact of the rare occurrence in this colony of a case of stone in the bladder, so rare in fact that there was not in the colony a single instrument for the operation of lithotomy, and one had to be sent from London.

The Epidemiology and Prophylaxis of Malaria in the Light of Recent Researches.—In this article A. Celli traces the life cycle of the malarial organism in man and the mosquito, discusses the habits of Anopheles, and deduces therefrom certain prophylactic measures which experience has also shown to be of service.

A Note on Species of Anopheles Found among Mosquitos Sent from Shanghai and Java.—George Thin pictures two specimens of mosquitos sent to him for examination from Batavia and Shanghai. They were both probably A. pictus, as appeared from a comparison with specimens of A. pictus and A. claviger caught in Spain.

The Saline Treatment of Dysentery.—W. J. Buchanan gives notes of five hundred and fifty-five consecutive cases of dysentery treated by a saturated solution of sulphate of magnesium, with only six deaths.

The Lancet, February 10, 1900.

Further Observations on Pernicious Anæmia; A Chronic Infective Disease.—In this final article of the series, W. Hunter calls attention to the relation between this affection and infection from the mouth and stomach. The nature of the infection is a mixed one, as it occurs in all classes irrespective of surroundings and as there is an abundant presence of organisms of coccal and short streptococcal nature forming zoöglœa-like masses amid the catarrhal and inflammatory exudation contained in the vomit. Treatment must include hygiene of the mouth and teeth, local treatment of the stomach and intestine, arsenic, and serum injections. The nature of the serum to be used is still to be determined.

Prognosis in Appendicitis.—From a series of two hundred cases H. A. Caley discusses prognosis as to recovery and as to recurrence. Under the former, he studies the pathological basis of prognosis from the nature and extent of peritoneal infection and the nature and course of the appendix lesion; the clinical basis requires the consideration of local symptoms, general symptoms, local signs and progress of the case.

Consanguineous Marriage and Deaf-Mutism.—A. H. Huth gives elaborate statistical tables, from which he concludes that when there is a family taint of deaf-mutism, more deaf-mutes are liable to be born in families in which there is a double inheritance through the relationship of the parents than when this is not the case.

A New and More Permanent Method of Mounting Amyloid Sections Stained with Iodine.—A. B. Green recommends the employment of Weigert's iodine, liquid paraffin, and xylol, with iodine crystals. Each is to be used on the section in the order named. A cover-slip smeared with vaseline is then placed over the section.

The Present Position of Aural Surgery.—W. B. Dalby thinks that the advance in aural surgery has greatly dispelled quackery, and calls attention to the vast amount of study which is now being given to the subject of chronic suppurative discharge.

Eighty Successive Cases of Stacke's Operation.—Full tables are given with an analysis of symptoms. Only three deaths resulted, and all these cases did not come under observation until a very advanced stage of pyæmic poisoning had been established.

A Case of Complete Inversio and Prolapsus Uteri.—F. L. Pochin records this case occurring in a primipara aged twenty years. Reposition was successful, and the puerperium was without special incident.

Fetichism in Surgery.—E. Stanmore Bishop thinks that the modern surgeon is especially liable to fetichism in two directions: undue importance attached to certain details in technique, and a desire to operate with a rapidity which is injurious to the patient.

Successful Case of Enterectomy for Gangrenous Hernia.—A. H. Burgess removed four inches of gut from a boy aged fifteen years. Healing occurred without suppuration, and the patient was up in three weeks.

Mental Dissolution.—A clinical lecture by G. H. Savage, in which he calls attention to the physical and mental peculiarities seen in persons passing into a condition of mental weakness.

Deutsche med. Wochenschrift, Jan. 25 and Feb. 1, 1900.

The Saliva and its Influence on Gastric Digestion.—Martin Cohn says the alkalinity of the saliva varies in different individuals and in the same individuals at different periods of the day. The average corresponds to a 0.0154-per-cent. solution of caustic soda. He never found an acid reaction, such as was noted by Sticker in the interval between breakfast and dinner. It has been suggested that retained products of metabolism may be got rid of by increasing the salivary secretion, but the author was unable to discover any evidences of such vicarious elimination in cases of renal disease. The digestive activity of the saliva does not cease with deglutition, but is continued for a time in the stomach. As has been shown by Van der Velden, there are two stages of stomach digestion. In the first the acidity is not sufficient to inhibit the saccharifacient action of the saliva (amylolytic stage), but in the second this action is arrested by the increased secretion of hydrochloric acid (proteolytic stage). It has been asserted by Sticker that the saliva has an influence also in the digestion of albumin, but Cohn does not think the experiments offered in proof of this assertion are conclusive. His investigations led him to the conclusion that the presence of saliva in the stomach is beneficial, but he was unable to determine that its presence was of extreme importance in digestion or that its absence impaired the process very materially.

A Case of Pneumathæmia.—Paul Bernhardt reports the case of an idiot, fifty-four years of age, who died after a brief illness marked chiefly by diarrhœa, anuria, and extreme restlessness. At autopsy the blood was found to be fluid and of a peculiar crimson tint. The heart, especially the left auricle and coronary veins, was swollen, and when opened under water its contained blood was found to be mixed with air. Incision of the inferior vena cava gave exit to a bloody foam. The liver was enlarged, its surface was covered with little vesicles, and on section a thin, bright-red foam exuded; the hepatic veins, when cut, gave exit to more air than blood. Examination of cover-glass preparations of the liver fluid showed the presence, in almost pure culture, of thick rods with rounded extremities, 1 μ thick and from 3 to 5 μ in length; there seemed to be an indistinct capsule; they did not form chains; they were stained by gentian violet, carbol fuchsin, and after Gram's method. The writer thinks it was probably the bacillus aerogenes capsulatus, which has been so carefully studied and described at the Johns Hopkins laboratory.

Clinical and Experimental Studies of Dural Infusion.—Paul Jacob gives an account of his experience with the injection of various fluids into the subarachnoid space after the removal of an equal quantity of cerebrospinal fluid through a lumbar puncture. The fluid must be injected very slowly (fifteen to twenty minutes being required for the passage of 25 c.c.); otherwise the most alarming pressure symptoms might be produced. Animal experiments with methylene-blue solutions showed that the fluid injected into the lower part of the subarachnoid space very quickly reached the brain, that it was eliminated very slowly, and that within a very short time it permeated the cerebrospinal substance. The writer reports a case of tetanus cured after dural infusions of antitoxin, and three cases of cerebrospinal syphilis treated most successfully by dural infusions of sodium-iodide solution. He believes there are great therapeutic possibilities in the treatment of many diseases of the central nervous system by this method of bringing the curative agent into direct contact with the diseased foci.

Employment of a Heart-Supporting Apparatus in Cardiac Affections, Especially in Cardiac Dyspnœa.—Abée, observing that patients with heart disease often instinctively make pressure with the hand over the cardiac region, was led to devise a mechanical support in which a pad should take the place of the patient's hand. He reports two cases of various cardiac affections in which the subjective symptoms, especially pain and dyspnœa, were markedly relieved, and the patients were able to take moderate exercise when previously they had been unable to walk without the greatest distress. The writer has studied the physical effects of the pad and finds that it elevates the heart as much at times as 2 to 3 cm. and causes an axial turning of the organ, as shown by the altered apex beat; the pulse is slowed by as much as ten beats in the minute; and finally the limits of lung expansion anteriorly on the right side are increased 1.5 to 2 cm. All these changes are constant, and occur within two or three minutes after the adjustment of the pad.

Treatment of Circumscribed Abscess of the Abdominal Cavity.—Sonnenburg cautions against rashly opening into the peritoneal cavity in suppurative appendicitis. A free and rapid opening of the abscess cavity is permissible only when the general symptoms are threatening and septic symptoms are present. In all other cases when it is a question of operating upon a circumscribed purulent collection, one should not immediately open the peritoneum, but should first seek for the abscess and evacuate it, and often the appendix will be found in the cavity. Great care should be taken not to break up the protecting adhesions.

A Specific Immunizing Serum against Spermatozoa.—Moxter injected guinea-pigs with the spermatozoa of rams, and found that the injected organisms gradually acquired a more potent spermatozoicide property. This power resided in the body of the guinea-pig, for the blood serum removed from the vessels did not possess it. The anti-body resulting from these spermatozoa injections is also hæmatolytic in relation to the red corpuscles of sheep.

Ileocolic Invagination.—Lewerenz reports a case of intussusception of the ileum into the colon through the ileocæcal valve occurring in a boy twelve years of age. The abdomen was opened, and the invagination was reduced with some difficulty. The patient made a good recovery.

Berliner klinische Wochenschrift, January 29, 1900.

Simultaneous Gunshot Wounds of the Thoracic and Abdominal Cavities.—F. Koenig concludes a lengthy article by a brief summary of the various pathological processes which follow injuries of this nature in the regions indicated. He calls attention to the fact that in addition to the injuries sustained along the course of the wound there may be severe lesions at a distance caused by the explosive force of the missile. Bacterial infection may arise not alone from the outside, but from the migration of germs from their natural habitat in the intestinal and biliary tracts. Products of inflammation may be removed by puncture. This failing, opening of the cavities is indicated.

The Surgery of Cancer of the Stomach.—H. Lindner discusses the question of possibly more radical intervention in the future. The removal of infected glands suggests itself and is to be attempted. On the other hand, recurrence in the glands is comparatively rare. In cases in which a radical operation is impossible, gastro-enterostomy is to be commended. In the latter class of cases it has been suggested that jejunostomy is the preferable procedure, but the author is not disposed to grant this point.

Therapeutic Employment of Moist Heat.—H. Davidson describes and figures an apparatus devised by him for this purpose. It consists essentially of a coil arrangement shaped to the human frame and supplied with a cover-lid. The coil is supplied with hot water from a reservoir to which is applied a spirit lamp.

Chronic Villous Polyarthritis and Arthritis Deformans.—By M. Schueller. A continued article.

Wiener klinische Rundschau, January 28, 1900.

Two Cases of Tuberculosis of the Serous Membranes in Man, with the Macroscopical as well as the Microscopical Appearance of Bovine Tuberculosis.—Josef Pelnár draws these conclusions from his observations on this subject. There exists in man a tuberculous affection of the pericardium and peritoneum which is characterized by small connective-tissue tumors with pedicles. Sometimes these are the only signs, then again there are besides these tumors other small tuberculous growths. These little swellings are both macroscopically and microscopically like the nodules in bovine tuberculosis. In these nodules tubercle bacilli are sparingly found, and show the morphological peculiarity that they almost always appear in little masses which are like those seen in actinomycosis. Cholangitis and pericholangitis tuberculosa hepatis can be seen as solitary thick-walled cysts of the size of a walnut, without other demonstrable tuberculous changes in the liver.

A Simple Method for the Application of Carbon Dioxide.—Rudolf Hatschek states that a good method of applying carbon dioxide is to take gr. lx. of sodium bicarbonate mixed with a little warm water, and with this mixture rub the patient. Carbon dioxide is evolved.

Wiener klinische Wochenschrift, February 1, 1900.

Air Emboli in Placenta Prævia.—Hugo Hübl says that diagnosis of this affection should be made: (1) By the exclusion of other possible diagnoses such as ruptures of the cervix and uterus, death from anæmia or from chloroform, and thrombus emboli. (2) If there is present over the heart a clucking murmur, and if in that region there is a tympanitic or dulled tympanitic percussion sound, then the clinical diagnosis of air emboli is certain. Hübl gives two conditions which make possible the entrance of air into the veins: (*a*) Pressure in the abdominal-uterine vessels is suddenly diminished, and so air is sucked into the open vessels. (*b*) Pressure in the interior of the uterus is increased, and in this way air within the uterus is pressed into the gaping vessels.

The Limitation of Laparotomy in Favor of Vaginal Cœliotomy.—F. Schauta believes that the improved technique of vaginal cœliotomy is one of the most valuable advances in modern operative gynæcology. Its mortality is about half that of the abdominal method. The course of healing is painless and uncomplicated, while there is an absence of suppuration and hernia, resulting from the operation, so common in the other method. As to the objections raised about "operating in the dark," he lays special stress on the fact that the technique should be so skilfully managed that the operation is under careful observation from beginning to end.

Ovariotomy per Anum.—Hubert Peters cites the history of a Russian woman, thirty-seven years old, who had from early youth suffered from constipation. For years she had noticed a rectal prolapse on defecation. On examination, a cystic tumor was also discovered, corresponding in position to the left ovary. In order to shorten the operation as much as possible on account of the precarious condition of the patient, ovariotomy was performed at the same time with the rectal operation by means of the anal method, instead of the usual abdominal or vaginal cœliotomy or the perineal or sacral method. The ovarian tumor proved to be a serous cystadenoma.

Bacilli of the Stools of Nurslings Colored by Gram.—Ernst Moro has isolated a bacillus from the stools of infants which he calls bacillus acidophilus because it flourishes in acid media. Tissier has also isolated a bacillus from the same source by means of anaerobic culture methods. Both are stained by Gram's method.

Münchener medicinische Wochenschrift, Jan. 30, 1900.

Contribution to the Question of the Causes of Death in Burns by Fire and by Scalding.—E. Scholz gives the results of two series of experiments made for the purpose of ascertaining the influence of the skin in the formation of toxins in the living body. First, he compares equally extensive burns, by fire, of the skin and peritoneum. Next, he compares burns of the skin—in the first place, skin with the circulating blood, then in a bloodless condition. He concludes that in scalding the skin changes do not play a chemical rôle, but that the chemical changes result from the influence of heat on the blood. In peritoneal burns a great number of blood corpuscles are changed. The burn of the skin, because of the protecting covering it affords, is not so destructive as the same injury of the peritoneum. Scalding of bloodless skin, which would, if the blood were present, cause death, is followed by no such effect in the anæmic part. This shows that the formation of toxic substances is not concerned with the skin. Neither do the blood changes occur through the absorption of toxic materials, but death by fire or scalding is due to the combined influence of the physical and chemical waste products of the blood resulting from the effect of heat.

Psychiatry in Relation to the Question of School Physicians.—W. Weygandt declares that the use of the school physician for the psychical observation of the students is still in the experimental stage. Psychology and pyschiatry are chiefly useful in the building up of this theory. The physician with psychological and psychiatrical education has the best foundation for the position of school physician in the higher schools of learning. In the public schools the students should be sifted and the weak-minded separated from the others and put in classes by themselves.

A Case of Acute Perichondritis and Periostitis of the Nasal Septum of Dental Origin.—Gustav Killian reports the case of a man thirty years old. Pain was severe, and foul-smelling pus escaped from the left nostril. The left second incisor ached. The mucous membrane of the nasal septum was opened and dressed. Six months later the patient again appeared, the tooth was extracted, and a cyst was disclosed. This was excised, and recovery followed.

A Case of Perityphlitis in a Hernial Sac: Resection of the Cæcum and Vermiform Appendix.—C. Göschel, after giving a history of this case, speaks of the literature on this subject. Diagnosis between incarceration and perityphlitis in a hernial sac cannot be made before operation. Happily this has little influence on the treatment of the affection. Operation is always indicated.

Severe Opium Poisoning of an Atrophic Child of Ten Weeks; Ten Hours' Faradization of the Phrenic; Recovery.—August Model reports the case of a young child to whom its nurse gave an overdose of the tincture of opium. He applied faradization to both phrenic nerves with the happiest results. After this treatment the infant, who had been very feeble, improved greatly in general health.

Experiments Concerning the Influence of New Antiseptics on Infected Corneal Wounds.—Wilhelm Hauenschild has experimented with protargol, silver nitrate, and oxycyanide of mercury of different strengths on infected corneal wounds, and finds the vitality of the micro-organisms in no way affected by the antiseptics. So far, mercury oxycyanide applied under high pressure has had the best results.

Absorption and Fat-Splitting in the Stomach.—By F. Riegel. A continued article.

La Riforma Medica, January 20 and 27, 1900.

The Action of the Halogens on the Cells of the Central Nervous System.—O. Modica and U. Alessi conclude from a series of experiments on guinea-pigs that the halogen salts, more especially bromides and iodides, profoundly affect the central nervous system. Changes in the chromatin constitute the first symptom, shortly followed by degeneration and necrosis of the cells. These grave lesions existed in animals which had apparently normally working nervous systems. The action of these salts does not differ from that of many other substances.

Acute Fibrinous Bronchitis.—Camillo Vittorio Pick reports a case noteworthy because of the rapidity of its onset and disappearance.

The Tetany of Influenza.—R. Gomez describes a case of tetany due to influenza in a child aged seven years.

Bulletin de l'Académie de Médecine, Jan. 23 and 30, 1900.

Respiratory Reflex and Lingual Tractions.—J. V. Laborde, describing his method of treating apparent death, says that the respiratory reflex is the first phenomenon of life in a newly born infant, and the first to be exhibited in the resuscitation of asphyxiated infants; so should it be the first in cases of suspended animation, or apparent death. The sensory nerves governing this function are the pneumogastric through the superior laryngeal, and the glosso-pharyngeal (as lately determined by the author). Rhythmical tractions of the tongue, by stimulating these nerves, excite them to renewed activity. The method is so simple, of such easy application by any bystander, that in cases of apparent suffocation, etc., it should invariably be tried. Laborde holds that after apparent death there is a latent period of life which lasts about three hours, and that it is during this time that rhythmical tractions of the tongue will often re-establish the respiratory function and restore the patient to life. Failure to obtain this result proves that death is real, not merely apparent. He urges the use of this procedure in every case of death for three, six, or twelve hours, either by means of the hand alone, or by the use of apparatus devised by him for the purpose.

Congenital Lacrymal Tumor.—M. Guéniot describes a case in a new-born infant. When pus formed, the lacrymal sac was emptied and cleansed, and two drops of a collyrium of 10 cgm. silver nitrate to 15 gm. distilled water was used morning and evening. A cure followed.

Abscess of the Liver.—Lucas-Championnière describes a case in which the radiograph was of use in determining the presence of a tumor. Exploratory puncture confirmed the diagnosis, and a curative operation followed.

The Chigre.—M. R. Blanchard discusses Clair and Joly's report of the recent appearance of the chigre or burrowing flea in Madagascar.

Dystocia.—M. Porak discusses a case reported by Narich concerning the diagnosis and prognosis of dystocia from fœtal hydrocephalus in breech presentation.

French Journals.

Invasion of the Lymphatic System in Cancer of the Stomach.—B. Cunéo makes a practical study of this subject, long one of theoretical interest. Anatomo-pathological data point out operative indications of great importance: (1) The frequent, almost constant, existence of submucous changes at 2 cm. beyond the apparent limits of the neoplasm, showing the necessity of cutting well beyond this limit. (2) The advance of the neoplasm along the lymphatic channels of the lesser curvature necessitates a wide resection of this region. (3) The habitual integrity of the duodenum permits of not including in the resection more than 1.5 or 2 cm. of this portion of the intestine. (4) The ganglia of the coronary chain and of the gastro-epiploic chain on the right side should be completely extirpated, so far as possible, at the same time as the tumor. (5) Pylorectomy is the best of the palliative operations in adenopathies at a distance, on condition of being easy and rapidly executed.—*Gazette des Hôpitaux*, February 1, 1900.

Some Ocular Disturbances in Typhoid Fever.—Edmond Koenig discusses optic neuritis and other eye affections in the course of typhoid which, like other severe infectious processes, may determine ocular changes. Optic neuritis is one of the accidents which may lead to atrophy and blindness. In doubtful cases we are no longer justified in admitting a meningitis in an exclusive sense, when such a lesion of the optic nerves is found. This ocular accident, occurring at times in the early period of convalescence, should make a reserve prognosis necessary from the double standpoint of general and local condition. Optic neuritis of microbic origin is possible without the intervention of other physiological or pathological mechanism.—*Le Progrès Médical*, February 3, 1900.

Osteo-Hypertrophic Varicose Nævus.—Klippel and Trenaunay relate an observation of congenital deformity in a man aged twenty-eight years, implicating the thigh, leg, foot, and portion of the trunk, consisting in a varicose nævus with elongation and enlargement of bones, causing slight limping. The condition had not changed essentially from a very early period. The literature is given, and the origin of such conditions is thought due to intra-uterine infection the effects of which persist after birth during the whole period of development.—*Journal des Praticiens*, February 3, 1900.

Primary Epithelial Tumors of the Bronchi.—Charles G. Nicolas finds that up to 1886 only eighty-six instances of primary epithelioma of the lung had been reported, and Pick in 1891 had found but fifteen cases of primary cancer of the trachea. The writer now collects thirty-five instances of neoplasms supposed by their observers to be primary cancer of the bronchus. He studies the whole question. The evolution is quite rapid and treatment is only palliative.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, February 4, 1900.

Hydatid Cyst of the Pleura.—Gibert and Jeanbrau put on record the case of a man aged thirty-two years, operated upon by Professor Forgue by resection of the eighth, ninth, and tenth ribs, evacuation of the pleural cavity, and cure, in hydatid disease originating in the liver. These cases are usually mistaken for simple pleurisy or tuberculosis. Ample thoracotomy at once is the best treatment to avoid lasting bronchial fistulæ and gangrene of the lung.—*Gazette des Hôpitaux*, January 25, 1900.

Experimental Typhoid Fever.—Paul Remlinger reviews the history, modes of inoculation, conditions which favor infection of animals, symptomatology, and pathology, and concludes that there exists in animals a true experimental typhoid, which is closely connected with typhoid of man, and that it presents in particular analogies with typhoid in infancy.—*Gazette des Hôpitaux*, January 27, 1900.

Jour. of Nerv. and Mental Disease, Jan. and Feb., 1900.

Progressive Ankylotic Rigidity of the Spine.—B. Sachs and J. Fränkel report several cases belonging to what they call the Strümpell-Marie type, which has an apparent resemblance to ordinary rheumatic affections, but differs from them in that the vertebral joints are affected; hereditary predisposition has not been established; the disease is progressive, has been noticed chiefly in men, and shows no tendency to improvement. The morbid changes causing this affection appear to differ in degree and localization, not in kind, from those found in extreme forms of articular rheumatism and arthritis deformans; but from a clinical standpoint "spondylose rhyzomélique" merits further study.

Trauma of the Cervical Region of the Spinal Cord, Simulating Syringomyelia.—James Hendrie Lloyd reports a case in which the anatomical findings were extensive destruction of the gray matter of the cord, and of the direct cerebellar and Gowers' tracts, with comparative exemption of the posterior columns. Correlating this with the clinical phenomena in the case, he thinks the inference warranted that the tracts for heat, cold, and pain pass up by way of the gray matter, eventually passing from the gray matter into Gowers' tract, while tactile or common sensation is conveyed by the fibres in the posterior columns.

Meralgia Paræsthetica.—John Herr Musser describes ten cases of this disease, which he defines as a disturbance of sensation on the external surface of the thigh, characterized by various forms of paræsthesia, associated with dissociation and more or less diminution of sensation. In statistics collected in regard to 99 cases, the affection occurred 75 times in males. The duration cannot well be determined. As to etiology, injury was mentioned 19 times, syphilis 10, alcoholism 8, typhoid 8, other infectious processes 8, pregnancy 6, gout and rheumatism 12, other nervous conditions 11.

A Case of Tumor at the Base of the Brain in the Pontine Region.—By James Hendrie Lloyd. See MEDICAL RECORD, vol. lvi., p. 138.

The Unity of the Acute Psychoses.—By Philip Coombs Knapp. See MEDICAL RECORD, vol. lvi., p. 137.

Two Cases of Muscular Dystrophy with Necropsy.—By William G. Spiller. See MEDICAL RECORD, vol. lvi., p. 140.

Anniversary Address.—By Wharton Sinkler. See MEDICAL RECORD, vol. lvi., p. 141.

The Nervous Equivalent of Fever.—By Henry S. Upson. See MEDICAL RECORD, vol. lvi., p. 137.

Landry's Paralysis.—By Philip Coombs Knapp. See MEDICAL RECORD, vol. lvi., p. 142.

A Case of Hæmatomyelia.—By James Hendrie Lloyd. See MEDICAL RECORD, vol. lvi., p. 141.

Annals of Surgery, February, 1900.

Pathology of the Lymphatics of the Peritoneum.—From observations based on over five hundred abdominal post-mortems, Byron Robinson concludes that there are in the adult certain localities of peritonitis which are practically constant: peritonitis over the right psoas muscle is found in seventy-five per cent. of the cases involving appendix, cæcum, and distal end of the ileum; over the left psoas involving the meso-sigmoid in eighty per cent. Lymphangitis over the levator ani in women involves about the same number. Examination of pieces from the areas of local lymphangitis shows nearly complete occlusion of the lymph-vessels. White connective tissue proliferates and constricts them. Means to transport infectious material is thereby wanting, and hence repeated lymphangitis becomes less and less dangerous.

Further Observations on Depression of the Neck of the Femur in Early Life, Including Fracture of the Neck of the Femur, Separation of the Epiphysis, and Simple Coxa Vara.—R. Whitman places on record another case of separation of the epiphysis in adolescence, and points out the essential differences between this class of cases and those of true fracture of the neck of the femur. Depression of the neck, either simple or traumatic, predisposes to progressive deformity, and may indicate operative treatment at an early stage as a preventive measure. Since forty-eight cases of this depression have come within the author's observation within a comparatively short time, he is inclined to believe that this deformity is more common than is generally believed.

Traumatic Rupture of the Bile Duct.—R. W Garrett records the case of a young farmer suffering from this injury as the result of a fall. Abdominal section revealed the rent at the back of the upper part of the common duct as it passes downward and to the left between the two layers of the lesser omentum. The patient recovered. Reference is made to other recorded cases.

Actinomycosis in Man, with Special Reference to the Cases which Have Been Observed in America.—J. Ruhräh reports seven cases, in addition to those previously published by him in the *Annals* These additions make the total of American cases seventy-two. The author believes that there are still additional unreported cases, and urges that the records be made complete with reference to this affection.

Inter-Scapulo Thoracic Amputation.—From the study of a large number of cases R. S. Fowler concludes that sarcoma of the humerus offers slight chance of ultimate cure by any but the most radical procedure, and that the operation of choice for sarcoma of any part of the humerus is primary inter-scapulo thoracic amputation.

The Technique of the Positive and Negative Diagnosis of Ureteral and Renal Calculi by the Aid of the Roentgen Rays.—C. L. Leonard makes a plea for the employment of this means of differential diagnosis, which he believes is perfectly reliable and in the light of our present knowledge an absolute clinical necessity.

Intestinal Obstruction due to Intussusception.—J. F. Erdman analyzes the histories of nine cases seen by him within a few years. Results of treatment were as follows: three operative recoveries, one enema recovery, four operative deaths, one non-operative death.

American Journal of the Medical Sciences, Feb., 1900.

Some Cases of Dilatation of the Stomach.—John H. Musser and J. Dutton Steele conclude from their observation of these cases that: (1) The symptoms upon which most reliance can be placed in determining the presence of gastric motor insufficiency are: (*a*) The presence of fluid and food in the stomach fasting over-night; (*b*) the ready entrance of fluid through the tube and difficulty in the return flow, (*c*) the absence of visible gastric peristalsis, (*d*) evidences of fermentation and intoxication by the products thereof; (*e*) thirst; and (*f*) scanty and concentrated urine. (2) In determining the position and size of the stomach, by far the most certain method has been inflation with air through the stomach-tube. (3) The condition does not seem uncommon in students. The etiological factor is myasthenia caused by chronic gastritis from the abuse of alcohol and tobacco, from deficient innervation, probably of congenital origin, and occurring in the course of acute disease.

Narcolepsy: A Contribution to the Pathology of Sleep.—D. J. McCarthy has found nothing in his studies of sleep and its disturbances to support the idea that the condition known as narcolepsy is a distinct neurosis or disease. In the only autopsy report out of eighteen cases collected by S. Weir Mitchell there was simply "no lesion." In Mitchell's case he found "starch corpuscles in those portions of the gray matter submitted to examination." McCarthy feels certain that a microscopical examination of the brain in such cases of prolonged sleep as that lately reported by Skerrit and Stewart, when the patient recovered from a sleep of fifty days with inco-ordination and other symptoms of brain lesion, would reveal cellular changes. He cites several interesting cases.

The Increasing Prevalence of Cancer as Shown in the Mortality Statistics of American Cities.—G. Betton Massey declares that the conviction is warranted that there is a widespread increase in the causes of this affection or the liability to acquire it, throughout the country. The greatest increase appears to have occurred in San Francisco. He gives nine charts representing the mortality rates of cancer in New Orleans, Philadelphia, Boston, New York City, San Francisco, St. Louis, Baltimore, England, and Wales, and one showing the combined cancer mortality of seven American cities. Aside from operations in private and in ordinary hospitals, the attention paid to this trouble may be said to be comprehended entirely in the establishment of one State laboratory of research and one special cancer hospital, the latter not confining its attention to cancerous diseases.

A Critical Summary of Literature on the Influence of Heredity on Deafness.—W. Scheppegrell states that there is a lack of unanimity of the views on this subject. In cases in which deaf-mutism cannot be traced to heredity or to consanguineous marriages, it may be the expression of an abnormal condition in the parent. It is a phase of physical degeneration which may appear in families suffering from scrofula, tuberculosis, mental or nervous diseases, syphilis, or alcoholism. Social environment is also of importance in this connection, as has been advocated by Ménière. Many nervous affections have been noticed in the families of deaf-mutes. Boys appear to be more frequently affected than girls.

A Case of "Family Periodic Paralysis."—James J. Putnam, in reporting this case, inclines to the view that in this curious disease we have to do with a subtle disorder of the physiological co-ordinations of health rather than with a general poison.

The Surgical Treatment of Acute Puerperal Sepsis, with Special Reference to Hysterectomy.—By Hiram N. Vineberg. See MEDICAL RECORD, vol. lv., p. 796.

The Practitioner, February, 1900.

On the Relation of Pneumonia to Pulmonary Tuberculosis.—R. W. Philip says such terms as tuberculous pneumonia and pneumonic phthisis should be dropped to avoid confusion. He is inclined to think that the concomitance of pneumonia and pulmonary tuberculosis in the same subject is commoner than is sometimes stated. His experience is that the supervention of pneumonia during the course of pulmonary tuberculosis is by no means uncommon, the already damaged lung falling more easily a prey to further attack. In this mixed affection there is a tendency of the pneumococcus to loiter, and he has found it present many months after the acute attack. As to the possibility of pneumonia determining the establishment of pulmonary tuberculosis, many authors are quoted. Some years ago the writer analyzed one thousand cases of pulmonary tuberculosis, and concluded that in only one-half per cent. was a close sequence of tuberculosis or croupous pneumonia to be made out. It is not a common precedent factor and is rarely found in immediately determinant relationship. In some supposed cases of croupous pneumonia the condition is really one of acute exacerbation of the tuberculosis.

The Surgical Aspects of Pneumonia.—A. Pearce Gould considers the surgical treatment of certain sequelæ, empyema, pulmonary abscess, gangrene of the lung, and briefly mentions the conditions under which pneumonia occurs in surgical practice. The surgical diagnosis of empyema is made with the aid of an exploring syringe. Every case of pneumococcus empyema should be submitted to operation as soon as the condition is diagnosticated. The surgical treatment of pulmonary abscess and gangrene consists in making a direct opening into the diseased area of the lung and evacuating the pus or removing the sphacelated tissue. The sign especially relied upon is the presence of moist râles. Pneumonia as a sequel to surgical operations may be due to too great exposure of the chest, but it must be remembered that the operation may take place just as an attack is developing. Broncho-pneumonia is a more frequent sequel to operation, due at times to aspiration of blood. Traumatic pneumonia is of limited area without tendency to spread unless infective organisms are carried into the injured lung.

On Some Methods of Treatment of Pneumonia.—Sir Hermann Weber confines his remarks to lobar, acute, or croupous pneumonia, comparing the treatment by blood abstraction, tartar emetic, opium, and salicylate of sodium, and the mortality of cases treated in Bonn and in London. In Bonn it was somewhat higher than in London (fourteen to seventeen per cent. as against twelve to fourteen per cent.). Epidemic pneumonia is more fatal than sporadic. He thinks an abortive treatment may be found by means of antitoxic serum. It is a possibility that different forms of pneumonic fever may be caused by different microbes. The prejudice against small doses of antimony and against bleeding in moderation in suitable cases is entirely unfounded, and both may be eminently beneficial.

On the Treatment of Pneumonia.—Sir Samuel Wilks says those who examine all patients thoroughly are the least likely to mistakes in diagnosis, confounding pneumonia with inflammation of the brain, delirium tremens, etc. If pneumonia reaches the stage of complete albuminization it is inevitably fatal. He doubts whether digitalis has a capability of lowering the pulse except given in doses which are probably injurious. None of the products of the laboratory can be compared with opium for long-continued use. He is satisfied when he sees a patient with pneumonia taking a dose of saline and five grains of Dover's powder every four hours. Cold to the chest and blisters are harmful. Pathology and therapeutics must go hand-in-hand.

American Journal of Insanity, January, 1900.

Case of Multiple Cerebro-Spinal Sclerosis of a Special Anatomical Form, with a History of Pronounced Family Defect.—I. H. Neff and T. Klingmann give a complete history of the case with postmortem findings. The interesting features are: (1) The distribution of the sclerosis, it being largely limited to the motor tract; (2) an absence of marked changes in the vascular system; (3) a pronounced secondary descending degeneration in the pyramidal tract and complete atrophy of the ganglion cells; (4) the reaction of degeneration and muscular atrophy.

Differential Diagnosis of Paretic and Pseudo-Paretic States.—A. W. Hurd makes special mention of cerebral syphilis and insanity of alcoholic origin. These are the cases which are most likely to develop paresis. Diagnosis is most difficult in the melancholic and demented types.

Common Features in Neurasthenia and Insanity; their Common Basis and Common Treatment.—G. W. Foster collates the results of other observers along this line, and makes a plea for the more general employment of hydrotherapy in cases of this nature.

Cortical Functions and Psychology.—H. Nicholas believes that much is to be expected from the psychologists in regard to determining the functions of the cortex of the brain, two-thirds of which is still a functional *terra incognita*.

A Differential Count of White Blood Corpuscles in a Few Cases of General Paralysis.—F. H. Jenks gives figures from nine cases, and thinks that they show an increased percentage of large lymphocytes at the times of a paretic seizure.

What the Chronic Insane can Accomplish under Proper Directions.—J. W. T. Rowe describes the work done at Central Islip, Long Island, and shows how beneficial out-door work is to this class of patients.

The Colony System of Caring for the Insane.—H. Ostrander warmly commends this system and describes an institution of this kind recently established by the trustees of the Michigan asylum.

General Pathology of Mental Diseases.—By H. J. Berkley; from advance sheets of "A Treatise on Mental Diseases," based upon the lecture course at the John Hopkins University, 1899.

Transitory Alienation following Intense Pain.—H. J. Berkley narrates a case in which the onset of symptoms was dependent upon the menstrual epoch.

Bulletin of the Johns Hopkins Hospital, January, 1900.

Contributions to the Surgery of the Bile Passages, Especially of the Common Bile Duct.—W. S. Halsted writes that he is much impressed with the splendid results of operations for gall stones in the common duct. He reviews eight of his recent cases, pointing out interesting facts in connection with them. In one case were conditions suggesting hepatico-cholecystostcholecystenterostomy as a possible operation. Remarkable toxic (?) renal colic resembling closely intestinal colic, associated with anuria; colic and anuria entirely relieved by salt infusion. In another case renal pains resembling intestinal colic (third observation of the kind within eighteen months). Halsted believes, if no contraindication exists, that adhesions should be separated if possible, as not infrequently to adhesions alone are due the symptoms which persist after the calculi have been removed or have escaped.

Medical Commission to the Philippines.—Lewellys F. Barker writes that at present the observations concerning the causation of dysentery—one of the most important results of the expedition to the Philippines being the isolation by Dr. Flexner, from the dejecta of patients, of a bacillus which is almost certainly the cause of the acute dysentery studied—the differentiation of the fevers of the region, the relative prevalence of typhoid fever and malaria, the studies of the varieties of the malarial parasite there found, and the investigations of beri-beri, may be specified as among the more important scientific results of the expedition.

Early Exploratory Operations in Tuberculosis of the Hip.—Joseph C. Bloodgood states that the chief object in the early operation for tuberculosis of the hip is to take the disease in its early stage, to relieve the tension of the distended capsule, to check and cure the tuberculous synovitis by disinfection and drainage, to explore the bone with the hope of finding the tuberculous osteomyelitis, in which case it can be partially or completely excised; trusting also to disinfection, drainage, and the healing-process to check and later cure the disease of the bone without injury to its continuity.

A Reconstruction of a Glomerulus of the Human Kidney.—William B. Johnston has made a wax model of a glomerulus of the kidney of a child three months old. When the child was dead but a few hours, the kidney was injected *in situ* through the abdominal aorta until the Berlin blue appeared in the renal vein.

Gunshot Injuries by Weapons of Reduced Calibre.—L. A. Lagarde declares that upon the whole, in the later Cuban war, the gunshot injuries by the Mauser, the reduced-calibre rifle of the Spaniards, were in keeping with those humane effects so confidently predicted by experimenters generally.

An Apparatus to Aid the Introduction of a Catheter or Bougie.—George Walker describes, with cut, an instrument whose object is to distend the urethral canal, and in this way to enlarge the narrowed portion, so that an instrument will pass through.

Archives of Pediatrics, February, 1900.

A Study of Lesions of the Liver in Young Children.—Rowland Godfrey Freeman gives a summary of his observations on hepatic lesions in young children. Fatty livers are frequent. The condition of nutrition apparently has no connection with this lesion. Fatty livers occur rarely in marasmus, malnutrition, rachitis, and syphilis, unless such condition be complicated by an acute disease; and with tuberculosis not more often than with other conditions. They occur most often with the acute infectious diseases and gastro-intestinal disorders. The two cases of cirrhosis of the liver examined by the writer ran a comparately acute course. The livers on section showed a marked hyperplasia of the so-called new-formed bile ducts. Focal necrosis of the liver may be a lesion of measles.

The Mortality and Treatment of Acute Intussusception.—Fred. Kammerer believes that after one failure of an attempt at reduction laparotomy is indicated. The causes of the high rate of mortality in irreducible cases are generally the septic condition of the intussusceptum, and the necessity of extended surgical interference. The mortality in reducible cases is less than half that in irreducible cases.

The Necessary Factors in the Successful Treatment of Intussusception.—C. L. Gibson thinks that the main feature of expected success in relieving intussusception depends, first, on the intussusceptum being found in a reducible condition and free from septic changes, and, second, that such a favorable condition can ordinarily be met only by a very early interference. That is, the prognosis depends absolutely on the promptness of relief.

Report of Two Cases of Sarcoma of the Lower Jaw.—W. H. Hudson states as particular points of interest: In Case I., the successful removal of the tumor and the uneventful recovery of the patient after the first operation. The necessity is also shown for the very early and thorough extirpation of sarcomatous growths if permanent relief is to be hoped for. In Case II. is the proof that a sarcoma may develop from a tooth follicle in a person eighteen years of age.

Bulletin of Cleveland General Hospital, October, 1899.

A Report of Several Cases of Typhoid Fever with Interesting Complications.—I. Friedman, in summing up the interesting points in five cases of typhoid fever, says that in Case I. the pus from the suppurated parotid did not contain typhoid bacilli, but a pure culture of the pneumococcus. Case II., complicated by intermittent malarial fever, further proves the possibility of double infection. In Case III., at the time of perforation, the temperature did not show the usual sudden drop. Case IV. tends to show that low enemas do not produce the desired result in securing free evacuation of the bowels and so prevent the serious complication of auto-infection; further, it shows that the use of decinormal saline solution has little effect on the conditions resulting from this complication. Case V. shows the not uncommon difficulty in making a differential diagnosis between miliary tuberculosis and typhoid fever. Tub baths produced a decided and prompt amelioration of many of the serious symptoms in these cases.

Osteomyelitis of Fibula with Spontaneous Casting Off of the Entire Bone, Empyema, Pyæmic Abscesses; and Recovery, with a Useful Limb.—J. C. Steuer gives the history of this case with the final results of his treatment. The leg was incised and the pus evacuated. The pleura was incised and drained and the various abscesses were opened. All the wounds were dressed with bichloride gauze and irrigated with 1 : 2,000 bichloride solution. Digitalis, nux vomica, and brandy were prescribed. The child recovered with very little trace of her severe illness.

Kryofin in Neuralgia.—Charles J. Aldrich's experience with this drug shows it to be safe in comparison with acetanilid, although it is as active. It is also safer than phenacetin. The purely neuralgic cases seem to be its field, and when used judiciously it rarely disappoints. It is often given in doses of gr. xv–xx., with excellent results.

A Case of Puerperal Mania with Albuminuria.—C. F. Dutton, reporting this case, believes that both the nephritis and mania were due to autotoxæmia. Whether the poison had its origin in the alimentary canal, in the liver, or in the more general metabolism of the body does not appear.

A Case of Appendicitis.—George W. Crile reports the substance of this case as follows: Rupture of gangrenous appendix; general peritonitis; incision and drainage; fecal fistula; resection with end-to-end anastomosis; ventral hernia, herniotomy, recovery.

Treatment of Stone in the Bladder.—C. B. Parker states that the successful treatment of stone in the bladder is always surgical. The two approved methods are: 1, litholapaxy; 2, lithotomy.

Guaiacol in Orchitis and Epididymitis.—William Huss notes the remarkable effects of guaiacol in these painful affections. It was first used on suggestion of Dr. Aldrich.

Report of a Case of Persistent Priapism.—W. J. Scott thinks that in this case the condition must be a reflex to the constrictor penis.

The Medical Chronicle, February, 1900.

Peripheral Neuritis following Chorea Treated with Arsenic.—J. C. Railton reports four cases which show that there is a risk of disastrous results following the treatment of chorea with arsenic, if that remedy is given in doses which amount in the aggregate to as much as six grains of arsenious acid. The results may give no warning of their approach during the administration of the drug, but make their appearance afterward with an interval varying from a week to a fortnight subsequent to its discontinuance.

Statistics on Lactation.—G. F. Blacker found that out of one thousand women of the lower classes in London, only twenty-four never suckled their children on account of an entire absence of milk, and of these only eleven were multiparæ.

The Edinburgh Medical Journal, February, 1900.

Vaginal Cœliotomy.—J A. C. Kynoch claims the following advantages for the vaginal over the abdominal route: Shorter convalescence, no abdominal cicatrix, consequently no risk of hernia or formation of intestinal or omental adhesions; less shock, drainage, if necessary, carried out through the posterior fornix. Cases suitable for the vaginal route (other means of treatment failing) he believes to be: Mobile retroflexion, causing symptoms at about the menopause; chronic ovaritis with adhesions; prolapse of the ovary with fixation; ovarian cysts if small; pelvic hematocele; unilateral, mobile, tubal swellings. Cases unsuitable are large tumors, old standing tubal disease with dense adhesions.

Sprue.—Lauder Brunton uses dilute solution of bicarbonate of soda to lessen the soreness of the mouth, and treats the sore anus with an ointment of bismuth and lanolin. The diet should be an entirely milk one.

The Treatment of Hypertrophied Prostate by Vasectomy.—T. Vincent Jackson says that this operation has never been followed by any kind or degree of harm, and that it has seldom failed to relieve the patient.

Pyosalpinx Removed by Laparotomy in the Early Puerperium.—R. Milne Murray successfully performed this operation on a patient two days after delivery. There was a good recovery.

Injuries and Diseases of the Conjunctiva.—A. Maitland Ramsay describes the various accidents and diseases which may affect the eye, and gives the treatment therefor.

Papilloma of the Tongue.—J. Grant Andrews reports a case in which many features suggested carcinomatous change. After removal there was a recurrence in the submaxillary lymphatic glands.

Sudden Death following Labor.—G. W. Simla Paterson reports a case in which unsuspected cardiac lesions and suddenly superadded pneumonia caused death twenty-four hours after labor.

Effects of the Roentgen Rays.—J. Hall Edwards reports three cases of lupus in which the use of the *x*-rays gave fairly satisfactory results.

The British Journal of Dermatology, February, 1900.

A Clinical Study of Some Winter and Summer Recurring Eruptions.—H. Radcliffe Crocker first considers acrodermatitis pustulosa hiemalis, a papulopustular winter eruption of the hands, probably a variety of folliclis. The winter diseases *par excellence* are chilblains, Raynaud's disease, pruritus hiemalis, and dermatitis hiemalis (Corlett). Three cases are given which agree fairly well with others described under a variety of names, including the one employed, folliclis. He says, in a foot-note, that since his paper was written he has read of a case described by C. W. Allen under the name necrotizing chilblain lesions, which seems closely analogous to his own, coming on only with the advent of cold weather. He described a recurrent pustular eruption of the hands similar to Corlett's dermatitis; a recurrent winter erythema causing red blotches upon the cheeks and about the mouth; an acneiform eruption limited to the nose; and a diffuse finely papular eruption. The recurrent tumor eruptions are vesico-pustular; vesicular, erythematous, and urticarial, numerous cases being cited, all except the acrodermatitis being of angioneurotic origin.

The Primary Lesion of Psoriasis.—William J. Munro points out as the result of studies in Sabouraud's laboratory that the initial lesion in psoriasis is a dry abscess in the superficial part of the horny layer of the skin; the vice of keratinization being secondary.

Dublin Journal of Medical Science, February, 1900.

Tropical Diarrhœa.—A. A. Gore discusses this question in the light of his military experience in India. During enforced residence in that country everything tending to lowered vitality should be avoided; habits should be regular, exercise moderate, diet unstimulating, and stimulants used only in moderate quantities. Flannel clothing must be constantly worn. On the supervention of diarrhœa, we may give a castor-oil purge guarded by a little opium. After that a most careful dietary is prescribed Later remedies include nitro-muriatic acid, lead, chloroform, bismuth, and carminatives.

A Contribution to Renal Surgery.—T. Myles discusses the question of bleeding in floating kidney, and gives the details of the method which he prefers for the fixation of this organ.

Dublin Fever.—H. Fitzgibbon studies a group of febrile symptoms which he attributes to unsanitary conditions in the city of Dublin. He considers the disease as an enteric influenza.

The Position of Murphy's Button in Modern Surgery. By J. S. McArdle. A continued article.

Il Policlinico, January 1, 1900.

The Action upon the Renal Function of Hypnotics Associated with Diuretics.—T. Pirocchi concludes from experimentation that chloral increases the diuretic action of caffeine and arbutin, occasionally that of diuretin and potassium nitrate, but that it has no effect upon sodium nitrate. The sulphate of duboisine increases the diuretic action of caffeine, sodium nitrate, diuretin, and arbutin, and sometimes of potassium nitrate. The most useful combinations are chloral and caffeine; chloral and arbutin; sulphate of duboisine and diuretin; sulphate of duboisine and the nitrate of sodium; sulphate of duboisine and arbutin.

Influence Exercised by Diphtheritic and Typhoid Toxins on Nutritive Exchange.—Domenico Pace concludes that a large but non-lethal dose of toxin causes a consumption of albumin, but exercises such an influence upon the delicate mechanism of nitrogenous exchanges that a second larger dose of the poison is felt only as a lesser dose which tends to economize the body albumin. This is what occurs when, in the study of the organic exchanges in an organism, repeated doses of toxin create a condition of opposition to infection, or what Charrin calls "the nutritive type of immunity."

Metabolism in Ankylostoma Anæmia.—Giuseppe Vannini gives the detailed results of observations in six cases.

Albuminuria in Diabetes and Renal Diabetes.—By Ferruccio Shupfer. A continued article.

Lo Sperimentale, Vol. liii., No. 4, 1899.

Hemorrhagic and Necrobiotic Infarcts in the Cirrhotic Liver.—A. Bonome holds that these are not due to the formation of connective tissue, although related to the obliterating endarteritis of the small branches of the hepatic artery and to the disappearance of the branches of the portal vein. The impeded circulation in the liver due to cardiac lesions or even to functional insufficiency of the heart facilitates the production of these infarcts. It also favors the action of the tubercle bacillus and its toxins and the development of connective tissue.

Typhoid Infection Without Intestinal Localization.—L. Picchi reports a number of cases in which there were no intestinal lesions, but in which the pathological and bacteriological researches gave unmistakable evidence of typhoid fever. As to the method of entrance of Eberth's bacillus into the system, that is as yet unknown.

The Spinal Accessory Nerve is a Mixed Nerve.—Gaetano Pieraccini states that recent macroscopical and microscopical researches have proved beyond a doubt that the eleventh nerve is a mixed nerve.

Results Obtained by Specific Serum Therapy in Malignant Pustule.—Achille Sclavo gives the statistics relating to one hundred cases. All but two resulted in recovery.

Norsk Magazin for Lægevidenskaben, January, 1900

The Temperature in Psychopathic States and its Importance in a Diagnostic Sense.—Harald Holm says that the body temperature is normally slightly higher in the evening than in the morning, and in the rectum than in the axilla. Any notable departure from this rule in either direction—that is to say, if the morning temperature equals or surpasses the evening, or the axillary the rectal, or if the evening and rectal temperature are two or three degrees Fahrenheit higher than the morning and axillary respectively—indicates a pathological condition. The author presents the results of a special study of temperature abnormalities in the hysterical and insane.

Hysterectomy in a Case of Fibroid Tumor.—O. Semb reports the case of a woman, forty-four years old, who had excessive losses with severe pain at the menstrual periods. Examination showed the presence of a submucous fibroid the size of a goose egg; the uterus was hypertrophied and completely inverted; there was no prolapse of the vagina. The uterus was extirpated and the patient made an excellent recovery.

Specialism and Massage.—Chr. Bergh argues in favor of the performance of massage only by specially trained experts, and reports a number of cases of various affections in which this mode of treatment rendered signal service.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 15, 1900.

William H. Thomson, M.D., President.

Report by Drs. Roswell Park and Gaylord upon their Researches on the Etiology of Cancer at the State Laboratory, Buffalo, N. Y.—Dr. Roswell Park, who read the first paper, dealt with the clinical portion, or border line of the subject. He said that Arnold had called attention to the comparative frequency of what he called "fragmentation" of cancerous tumors, but others had claimed that this was a post-mortem change. Leucocytic aggregation and infiltration must be regarded as a reaction against some form of irritation. Leucocytic infiltration or phagocytosis was practically always the reaction against extraneous forces. The mechanism of lymphatic enlargement had not been made so clear yet as it should be. To his mind, every metastasis had the force and significance of an inoculation experiment. Secondary nodules in the involuntary muscles at a distance were very rare. Diffusion of cancer along the nerve trunks was very interesting, and was more frequent than was commonly supposed. Involvement of surfaces constantly in contact had been known to furnish numerous instances of the spread of cancer. That immediate contact was not necessary, was shown by cancer of the lip and tongue. Cancerous elements, when introduced into the serous fluids, seemed to find very favorable conditions for their development. A number of observers had succeeded in transmitting tumors from one animal to another of the same species. Syphilitic lesions, or their resulting scars, might be points of departure for cancerous formations. Fistulous tracts, especially those leading inward from the skin, with a gradual downward extension of the epithelium of the skin, had often been the starting-point of cancer. Scars were particularly prone to undergo cancerous change, and this tendency was the more marked in proportion as the nutrition of the scar tissue was lowered. For this reason, cancer was liable to attack scars following extensive burns. About the vulva, as well as about the tongue, slight but prolonged irritation or traumatism was a common source of cancer. One observer had reported no less than six cases, in which cancer of the uterus had been apparently the result of traumatism, inflicted by the use of a pessary. Of forty-eight cases of cancer of the liver reported by one observer, forty-one gave a history of gall stones. The speaker said that he had recently seen a marked case of multiple sarcoma, originating in what had been apparently an innocent nævus. In the mucous membrane of the alimentary canal similar changes were noted. Uterine adenoma certainly predisposed to cancer of the uterus. Dr. Park did not believe in the heredity of cancer, although he expressed his belief in a hereditary transmission of a soil favorable to the growth of cancer. He carefully distinguished between the cancerous dyscrasia, the forerunner of cancer, and the cancerous cachexia, the result of cancer. Apparently, cancerous cachexia was a complex product of numerous factors, though characterized in general by toxic phenomena. In this connection one should not lose sight of the effect of frequent and exhausting hemorrhages, and the common association with renal disease.

Dr. Gaylord made some remarks on the pathology of cancer, illustrating them with lantern slides. He said that the most prominent school in this line of recent research was the Italian school. He characterized Bras as an ignoramus, and his work as being in the hands of a charlatan. He had exhibited to the speaker some of his peculiar organisms, and these had been at once recognized as nothing more than common contaminations. Russell, of Edinburgh, eight or nine years ago had described what was now known as "Russell's fuchsin bodies." They occurred with sufficient constancy in cases of cancer to make Russell describe them as having an etiological relation to cancer. It had been soon found, however, that many other bodies having no pathological significance whatever also stained readily with fuchsin. Dr. Gaylord said that, from our present knowledge, it was not at all improbable that these so-called fuchsin bodies might, after all, have some definite relation to cancer. Shortly after Russell had come Walker and Plimmer. The latter investigator had stained twelve hundred carcinomata, and had found in these a certain organism, which could be injected into animals, and could be recovered from the tissues of these animals. Plimmer had not, however, succeeded in reproducing the phenomena of cancer by such inoculations. He had demonstrated that this organism was a species of yeast, and that it gave rise to certain well-marked pathological changes. The speaker then discussed pathogenic yeasts, and their bearing upon this subject. He stated that it had been only comparatively recently that a pathogenic yeast had been known to exist. Botanists had not yet definitely determined whether the yeast represented a definite form, or only a transition stage of a higher organism. It was probable that it existed in two forms, one being a pathogenic fungus. The most exhaustive research showed that it was so far impossible to classify yeasts morphologically. He had employed Plimmer's technique recently in twenty-five cases of carcinoma, and in every instance had found Plimmer's bodies therein. These organisms had been occasionally cultivated, and hence it was not probable that these bodies were degeneration products. Concerning the work at the State cancer laboratory in Buffalo, the speaker said that those working there had exhausted all the classical methods of investigating the nature of cancer. They had once succeeded in producing carcinoma by inoculation with the organism referred to. Their recent experiments had embraced prolonged and thorough drying of infected lymph nodes, proved by the microscope to contain Russell's bodies, and the injection of the powdered product into animals. In each instance the animal had died within three or four weeks, and the lymph nodes had been found generally enlarged, and had been shown by the microscope to contain large numbers of Russell's bodies. He thought it probable that if these bodies bore an etiological relation to the tumors, it was a very broad one, and probably would be found related to all forms of rapidly growing tumors.

THE PRACTITIONERS' SOCIETY.

One Hundred and Fifty-Second Regular Meeting, Held on Friday, January 5, 1900.

A. Alexander Smith, M.D., President, in the Chair.

A Case of Recurrent Retinal Hemorrhages.—This was presented by Dr. E. G. Janeway. The patient was a man, thirty-eight years old, who had suffered from four attacks of hemorrhage into the retina. In the first attack, which occurred about four years ago, there was a hemorrhage into the retina of both eyes; in the two subsequent attacks only the left eye was involved, and in the last attack the right eye. Dr. Janeway said the case was interesting on account of the location of the hemorrhages, and because no adequate reason could be assigned for them. They occurred when the patient was fatigued or while he was suffering from a cold or coryza. The man's heart was a little enlarged, and there was a faint systolic murmur on one examination. His urine was generally loaded with urates. There had been no hemorrhages elsewhere, and nothing of the nature of purpura. The sight of both eyes was much impaired, particularly the right. He had had rheumatism in earlier life, and diphtheria some nine years ago.

Dr. Charles Stedman Bull, after examining the patient's eyes with the ophthalmoscope, said he regarded the case as one of chorio-retinitis disseminata, the inflammatory process being primarily in the choroid, with resulting hemorrhages. In one eye an extensive hemorrhage involving the macula had been followed by a large atrophic patch, leaving nothing but the sclera. The right eye was the more seriously involved. The lesions were more numerous at the periphery than in the centre of the field in the left eye. The blood-vessel walls did not show any ophthalmoscopic evidence of disease, and the speaker said he thought the cause of the trouble was in the blood rather than in the vessel wall. In the left eye the nerve was still perfectly healthy, well nourished, and normal in appearance, but around the optic discs in both eyes there were marked degenerative changes in both retina and choroid. Dr. Bull said he thought the original cause of the trouble was some blood disorder, possibly rheumatic, producing an ophthalmoscopic picture totally different from that observed in cases in which the vascular walls were diseased.

A Case of Primary Intrathoracic Growth of the Left Lung.—This case was reported by Dr. Janeway. The patient was a man, forty-seven years old, who had been in good health until last September, when he began to complain of shortness of breath. His previous history, as well as that of his family, was negative; he had never had syphilis nor met with an accident. When Dr. Janeway first saw him, about three weeks ago, the dyspnœa was very pronounced. There was swelling of the neck and lower part of the face, and the patient complained of a throbbing in his head. Examination showed an intrathoracic growth which had replaced the upper lobe of the left lung. The veins of the neck were swollen and congested, and a superficial vein about as large as a lead pencil, beginning about the sixth rib, ran down the left side of the chest to the level of the umbilicus, with its current of blood downward. The speaker said he attributed this to interference with the current of blood in the vena azygos, internal mammary, and some of the intercostal veins, causing a reflux of the blood. Dr. Janeway said he regarded the intrathoracic growth in this case as a sarcoma or carcinoma, probably originating in the mediastinum, on account of its rapid growth and the marked pressure symptoms it had given rise to. The man was now scarcely able to walk across the floor. Intrathoracic growths, Dr. Janeway said, were more common than was usually believed. During the past year, four such cases had come under his observation. In one, which he saw about three weeks ago, death occurred suddenly as the man was turning over in bed. That patient had been under treatment for months for severe intercostal neuralgia. He then developed some pleurisy and subsequently symptoms which indicated the presence of an intrathoracic growth, which proved fatal. In another case which he saw last spring, the patient, a lady, was supposed to be suffering from pulmonary tuberculosis. Over the left lung there was marked flatness, with loss of vocal fremitus, and paralysis of the left recurrent nerve. There were no fever and no special distress; there was very little displacement of the heart. Subsequently, the disease affected the other lung, and pleurisy with effusion developed. The patient died of suffocation within five days.

Dr. Janeway also reported the case of a woman whose cousin had died of sarcoma of the pleura. Two years before her death she had an attack of pericarditis in the course of slight rheumatism. From this she made a complete recovery, and the examination of the lungs showed no evidence of disease. About a year before her death she began to complain, and an examination showed a progressive solidification of the left upper lobe with dulness and bronchial breathing. Gradually fluid took the place of the lower lobe, while the side of the chest did not enlarge nor did the heart become displaced; neither was there any fever present. Some of the fluid in the lower part of the left chest removed for diagnosis was of low specific gravity, without blood or diagnostic cell contents. From these factors the diagnosis of carcinoma of the left lung with retraction was made. Toward the end of life a nodule made its appearance in the left breast, which had previously been free. At the autopsy the left lung had the appearance of a chronic pneumonia. The lung was of a grayish color, retracted, and a clear fluid filled the rest of the pleural space. Two secondary cancerous nodules were found in the right lung, two in the liver, and one in the left breast. The reasons for the diagnosis of cancer before death were given above. Even at autopsy this case might have been mistaken for chronic pneumonia.

Dr. Robert F. Weir said the subject of intrathoracic growths was interesting from a surgical standpoint, particularly those occupying the mediastinum. Growths in this region were of more common occurrence than was generally supposed. Of the malignant neoplasms, carcinoma was the most frequently observed, and in such cases surgical interference was of very little avail, but when the anterior or posterior mediastinum was the seat of a benign tumor, due perhaps to enlargement of the glands in that region, the possibility of surgical relief from such pressure effects should be borne in mind. A certain amount of success had already been achieved by operating in these regions. Posterior incisions, through which the œsophagus and growths in the posterior mediastinum may be reached, were known to all the members. Anteriorly, Milton, of Cairo, had shown that much could be done by splitting the sternum nearly its whole length and retracting the two sections of the bone for a distance of from one to two inches, thus obtaining free access to the anterior mediastinum. Others, with the same object in view, proposed division or ablation of the sternum high up. Dr. Weir had in one instance been able to reach behind the sternum to a distance of nearly one and a half inches below its notch.

Dr. George L. Peabody related a case of primary carcinoma of the lung which came under his observation on the autopsy table some years ago. The patient was a man whose only symptoms of pulmonary trouble made out during life were those of a bronchitis. His most prominent symptoms, for which he had been treated for many weeks, were of spinal origin. There was evidence of pressure on the cord in the dorsal region, with intense pain, ultimately paralysis, and death from exhaustion. The autopsy showed a diffuse development of carcinoma in both lungs, with a secondary large growth involving the dorsal vertebræ and the muscles of the back. The disease had undoubtedly originated in the lungs, yet the symptoms referable to those organs were very trifling.

Treatment of Hernia of the Sigmoid Flexure.—This paper was read by Dr. Robert F. Weir (see page 309).

Dr. Joseph D. Bryant said that his experience with hernia in the region described by Dr. Weir was not very extensive; he had seen two cases of cæcal hernia and one of sigmoid. In his first case of cæcal hernia he was prompted to suspect that he had to deal with this condition—or at least with some form of hernia which was not properly provided with a sac—because there was no history of any definite periods of reduction, such as commonly occurred in a hernia which was provided with a proper sac. Then again, the outline of this hernia, which was not strangulated, was different from that frequently observed. An incision was made in the usual way, but lower down, and after exposing the intestine and liberating the connective-tissue adhesions lying between it and the adjoining structures, the hernia was quite easily pushed back. No gangrene or other unfavorable symptoms resulted. The man was discharged from the hospital and lost sight of, so it was impossible to say whether a recurrence took place or not. In the second case of cæcal hernia, which was strangulated, the operation proved more difficult. Reduction was accomplished only after free separation of the tissues, with division of the restraining bands on either side, including the peritoneum. The patient made a good recovery. In the case of sigmoid hernia, Dr. Bryant said he did not suspect this condition of affairs until the time of operation. Reduction was comparatively easy because of the fact that the intestines were better provided with peritoneum than was usually the case. In operating on this class of cases, the speaker said, care should be taken not to employ too great force, and interference with the vascular supply should also be avoided. In the next case which might chance to come under his observation, Dr. Bryant said he would resort to the method described by Dr. Weir.

Dr. Charles McBurney said he had seen four cases of hernia of the sigmoid flexure possessing the peculiarities which Dr. Weir spoke of. He had never recognized the condition prior to the time of operation, the external signs having been those of ordinary left inguinal hernia. Aside from the confusion arising from failing to find the usual hernial sac, Dr. McBurney said he experienced no special difficulty in dealing with the cases. In each instance the mass was returned to the abdominal cavity by means of blunt dissection and gentle manipulation, and then the wound in the abdominal wall was closed in the usual way. The cases did well, and recurrence had not taken place when they were last heard from. Dr. McBurney said he did not think the danger of impairing the vascular supply of the intestine deserved much consideration, unless the dissection was carried too close to the intestine. As soon as the true condition of affairs was recognized care should be taken to make the dissection as far away from the intestine as possible, so as not to interfere with the plexus of vessels running into the gut. Of course, if the dissection was made very close to the wall of the gut, every stroke of the knife divided so many supplying vessels. Dr. Weir mentioned several cases of intestinal fistula resulting from defective vascular supply of the gut, but in connection with such a statement the kind of wound healing which followed the operations should also be known. If clean, aseptic healing was obtained, the speaker said he would feel absolutely safe about the nutrition of the gut, but if suppuration occurred he would feel afraid that the vascular supply of the gut might suffer. The method of peritoneal covering described by Dr. Weir, the speaker said, he had never seen employed; from the description, it appeared to be an attractive method of dealing with such cases.

Dr. Weir, in closing, said that the cases which he had collected from the French literature did not always give the details of the operation. He was therefore unable to say how much dissection was done, but he was inclined to believe that a good deal of force had been employed in replacing the bowel. He said that two classes of this form of hernia were met with; in one class the gut was comparatively loosely attached and could be pushed back without much trouble and retained there, but there were other cases in which, because of inflammation, or long residence *in situ*, or slight traumatism, the connective tissue became dense and a certain amount of dissection was required. Of course, it was better to cut widely, but the most important factor to remember was to employ no force in manipulating the gut. As regards the healing of the wounds in the cases he had quoted, Dr. Weir said the operations had been done by well-known surgeons, and he was inclined to believe that they worked with proper antiseptic precautions.

Dr. Bryant said he had recently operated on a woman for recurrent appendicitis, and found that the appendix arose from a posterior fibrinous band of the ascending colon, at the junction of its upper and middle third. The speaker said he had never seen or read of anything of the kind before. The patient made an uneventful recovery.

Dr. Charles Stedman Bull said that at the previous meeting of the society Dr. Kinnicutt had reported a case of acromegaly, and the patient had subsequently had an ophthalmoscopic examination. This had proved absolutely negative, as far as any pathological conditions of the optic nerve were considered, much to Dr. Bull's surprise. The speaker said that well-marked cases of acromegaly generally showed advanced signs of atrophy of the optic nerve.

Chorea and Tænia.—Dr. Andrew H. Smith reported the case of a boy, twelve years old, who suffered from chorea, and had a distinct cardiac lesion. He was treated for a long time without much benefit. Recently, the nurse discovered some flakes of tape-worm in the stools, and upon the expulsion of the worm the chorea readily yielded to treatment. It disappeared within a week after the tape-worm was expelled.

Dr. A. Alexander Smith said it was not uncommon to see choreic manifestations in children suffering from tape-worm.

Dr. Beverley Robinson said he was recently called to see a woman who was suffering from what was apparently a severe attack of bronchial asthma, with marked cardiac depression, cold extremities, and a condition bordering on collapse. Her symptoms, it appeared, had been induced by some tablets which her husband had given her for the relief of a "cold." The tablets were made by a patent-medicine concern, and Dr. Robinson said he was unable to learn their composition.

Typhoid Bacilli and the Gall Bladder.—Dr. Weir said he was recently called to operate on a woman who, about a month before, had recovered from an attack of typhoid fever. Recently she had been seized with a severe pain in the region of the upper abdomen, and on the right side a tumor was made out, which was recognized as a distended gall bladder. This was opened, and about six or eight ounces of a tolerably clear glairy fluid and some pus were evacuated. This was sent to the pathologist for examination, who reported that it contained large numbers of typhoid bacilli. The gall passages, it was supposed, had become temporarily blocked by a catarrhal swelling. Though a number of such cases had already been reported, yet they were comparatively rare and obscure. Dr. Weir asked whether any of the members present had observed similar cases.

Dr. Andrew H. Smith said he recently saw a young woman convalescing from typhoid fever; her temperature was normal, when she was seized with what was apparently an attack of hepatic colic; there was tenderness over the region of the gall bladder, and an ill-defined tumor could be made out.

Dr. Walter B. James mentioned the case of a boy, aged twelve years, who very early in the course of typhoid fever developed jaundice, with severe pain over the gall bladder, and some enlargement of that sac. His symptoms were regarded as the result of a catarrhal condition of the gall ducts. The patient went on through a mild attack of typhoid fever, from which he made an uneventful recovery.

Dr. Weir said that certain German observers regarded the mucous secretions of the gall bladder as a very good medium for the cultivation of the typhoid bacilli.

Dr. Janeway said this subject was now being studied at the Johns Hopkins laboratory.

Dr. Peabody said the fact had been recognized that the gall bladder could be infected by the typhoid bacilli. In the case referred to by Dr. Weir, there had been a previous attack of biliary colic some years ago.

Dr. Janewav said the fact that in Dr. Weir's case a light glairy fluid was evacuated, indicated a stoppage of the cystic duct. The speaker said he had recently seen a woman who was quite indignant because an operation for gall stones had not saved her from a recurrence of the same trouble. She had had four attacks of gall-stone colic during the past six weeks, three months after the operation, and in three of them she passed gall stones. Another patient, a man, was operated on by Dr. Bull, who removed a stone from the common duct by opening the duodenum. A year later, at a second operation, another stone was removed. The patient now wished to know whether he could get rid of his gall stones by other than surgical means.

Dr. McBurney said it had never been claimed that these operations prevented the formation of gall stones. If, after the operation, nothing was done to prevent the formation of the stones, recurrent attacks were apt to occur.

Dr. J. W. Brannan said that it had been suggested that the bacilli in the gall bladder might be the direct agent in causing relapses in typhoid fever. So long as the bacilli remained in the bladder, they apparently did no harm, except perhaps locally. It was probable, also, that they might be discharged into the bowel without reinfecting the patient, provided this did not occur until after he had become immune against a second attack of the disease. If, however, this occurred before immunity had been acquired, the patient was liable to suffer a relapse. This view enabled us to account for the relapses which so often followed upon indiscretions in diet before convalescence had been thoroughly established. The more liberal diet stimulated the liver, and caused an increased flow of the bacteria-laden bile into the intestine, at a time when the patient was not protected against infection. In support of the opinion that typhoid bacilli were an etiological factor in the formation of gall stones, Keen in his "Surgical Complications of Typhoid Fever" stated that typhoid bacilli had been found by several observers in the gall stones themselves, and in some cases apparently serving as a nucleus.

Dr. Robinson reported the case of a boy, who was treated at St. Luke's Hospital for typhoid fever. He apparently made a good recovery, and as he had been without any fever for at least eight days, he was allowed to go home. For some days previous to his discharge, his diet had been practically unrestricted. On the night of his arrival home, he had a high fever, and when Dr. Robinson saw him the next morning his temperature was 102.5° F. He was sent back to St. Luke's Hospital with a relapse which had lasted for several weeks. Dr. Robinson said he could explain the relapse only upon the basis that reinfection had occurred through the gall bladder.

Dr. James said he had seen a relapse occur as long as twenty-eight days after an attack of typhoid fever.

Dr. Peabody mentioned a case in which a relapse had occurred after three weeks.

Correspondence.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

Writing as I do at the beginning of the second week in February, I have no new information to transmit to you from the seat of operations, as matters have been for the past ten days at a complete standstill. At Modder River the camp is healthy, and there have been no casualties. The stories that the Boers in the trenches just ahead of Lord Methuen are suffering severely from typhoid fever and smallpox are all perfectly untrue. With General French's column a few casualties have occurred, but there has been no actual engagement on the Free State frontier; and while the present lovely weather lasts in South Africa the medical department of the forces is not likely to have much to do unless as a direct result of fighting. From Ladysmith the cheering account comes of a better state of health; the spread of typhoid fever has apparently ceased, and with this cessation the urgency to relieve the city has disappeared. Sir Redvers Buller has probably come to an understanding with Lord Roberts that he will not attack again till Lord Roberts is ready to move up also, a policy which the better public health of Ladysmith now renders practicable.

The Irish Hospital.—Lord Iveagh's hospital equipment, which is known as "the Irish Hospital," left Dublin for the Transvaal on February 3d, and had by far the most enthusiastic and popular send-off that has been accorded to any of the numerous bodies of men who have left Dublin for the seat of war. In Ireland the feeling among the lower orders, which it must be remembered is reflected by the members of Parliament, is more pronouncedly in favor of the Boers than it is in any other part of the kingdom. Many English and Scotch regret the war most sincerely, but all, whether they think the situation to have been inevitable or to have been brought about by faulty diplomacy, greedy capitalists, or ambitious politicians, hold that, being in the quarrel, Great Britain must bear herself as one that eventually intends to win. When the war is over, let the recriminations come. Not so many of the Irish people; so sincere is their hatred of England that they desire the Boers to win, although the most determined soldiers in the army that is fighting against the Boers are Irish by birth and recruited in Dublin. The "Irish Hospital," however, came in for no expression of ill-will; on the contrary, the aims of its generous donor and its staff were recognized in the heartiest way by the citizens. The hospital corps was played out of barracks by the band of the Royal Irish Constabulary, and marched through densely crowded streets to the North Wall. The whole line of the quays was a mass of cheering men and women, who made it sufficiently clear that all good wishes went to South Africa with the departing hospital and its officers. Dr. George Stoker was in command, Sir William Thomson, ex-president of the Royal College of Surgeons of Ireland and chief surgeon to the hospital, having previously started for the seat of war.

The Imperial Yeomanry Hospital Staff.—When the superior mobility of the Boers to the British—not to say the absolute uselessness of infantry attacks delivered point-blank against an ambushed enemy—had been demonstrated by three or four serious reverses, the British government decided to send out to the Transvaal ten thousand mounted volunteers. These, the Imperial Yeomanry, required to be supplied with a complete hospital equipment, and the personnel of the medical staff to accompany the hospital has now been announced. It is as follows: Lieutenant-Colonel A. T. Sloggett, R.A.M.C., military commandant of the Imperial Yeomanry Hospital and principal medical officer; Mr. Alfred Downing Fripp, assistant surgeon to Guy's Hospital, chief civilian medical officer; Dr. John Wichenford Washbourn, physician to Guy's Hospital; Mr. Raymond Johnson, assistant surgeon to University College Hospital; Mr. F. Newland Pedley, dental surgeon to Guy's Hospital; Mr. L. Vernon Cargill; Mr. Hamilton A. Ballance; Mr. William Turner; Mr. John F. Hall Edwards, surgeon-radiographer and photographer; Mr. Wallace C. G. Ashdowne; Mr. J. S. Christopherson; Dr. Andrew Elliot; Dr. H. W. Saunders; Mr. L. E. C. Handson; Dr. H. W. Bruce; Mr. A. P. Parker; Mr. G. E. Richmond; Mr. R. T. Fitzhugh, and Mr. Barclay Black.

The Excellence of the Medical Arrangements at the Seat of War.—On all hands it has been allowed that the medical arrangements in the Transvaal have been excellent. Correspondents with Buller's column and with Methuen's column alike have said that the Royal Army Medical Corps have discharged their duties both in the front and at the base, on the march and under fire, with calm and deliberate attention. There has been no sacrifice to display and no hurry. The wounded have been quickly collected, rapidly dressed, and comfortably transported to hospital. There has been but one voice dissenting to this view, a view that has been adopted upon the authority not only of special correspondents of all nations and of the medical press, but upon the direct reports of Lord Roberts, Sir Redvers Buller, and Sir Willam MacCormac. But an anonymous correspondent of *The Times*, writing late in January, sent back a message to England to the effect that the arrangements of one of the big base hospitals at Wynberg were bad, and that there was disagreement between the R.A.M.C. and the Red Cross organization. *The Times*' correspondent was quite inaccurate, and telegrams from the highest authorities at the Cape gave his assertions direct contradiction, and people are wondering how *The Times* came to print the insinuations and why the government does not print the rebutting telegrams.

Coxalgia with Abscess.—Iodoform in ether is painful as an injection; camphorated naphthol is toxic. Under camphorated menthol healing takes place in seventy-five per cent. of cases.—Ménard.

IDENTITY OF DIPHTHERIA AND MEMBRANOUS CROUP (?)—A COUNTRY PROTEST.

To the Editor of the Medical Record

Sir: It is taught and supposedly believed by the profession that these diseases are one and the same. I cannot think so, and I wish to state some of the reasons why I cannot. There is, I know, a diphtheria of the larynx, contagious and capable of reproducing itself in larynx or pharynx, nares, and elsewhere; but there is also another disease of the larynx, which we country practitioners call membranous croup, not specific in character, whose origin is much the same as that of pneumonia, and which is no more contagious than pneumonia. It originates sporadically and does not propagate itself. The desolating track of diphtheria by a little investigation may always be traced before and after, while in my observation this croup blew where it listed, and no man knew whence it came or whither it went. In many cases I have seen it have every opportunity of contagion, yet contagious it has not been in a single instance. Time and again have I seen it in the same house, in the same log cabin, in the same room, in the same bed with other children, yet no contagion. Often have I seen other children tucked under the same coverlet ere the "light that failed" dimmed in the eyes of the sick one; yet no contagion. I have seen little brothers and sisters kiss the dying forehead and mouth; yet no contagion. I have seen mothers hold the stertorous mouth of their gasping three-year-old to their breasts for hours, and then with unwashed hands, with unchanged dress, nurse their infants through garments sodden with the sick one's breath; yet no contagion.

Further, observation has given me some hope in the treatment of diphtheria, but this croup ever brings its rope and black cap, and I stand by its bedside as helpless as a mother by the gallows of her law-doomed child. I am compelled, therefore, to believe that, if these diseases are the same, "it is a sameness with a difference," both as to contagiousness and fatality, and different I assuredly believe them to be. I am aware that my limited experience entitles my opinion to little weight, yet I am convinced that if country practitioners will lay aside their fear of being accused of bucolic ignorance, and, like Sairey Gamp, "speak as they find," their aggregate voice will give my opinion substantial approval.

S. M. Worthington, M.D.

Versailles, Ky.

GUARDING AGAINST THE PLAGUE IN JAPAN.

(From our Special Correspondent.)

Tokio, January 12, 1900.

Preparations on a very extensive scale are being made to meet the epidemic of the pest, which it is feared will break out in the spring. The total number of cases up to the present time is fifty-five; namely, twenty-seven in Osaka, twenty-three in Hyōgō, and one each in Fukuoka, Nagasaki, Wakayama, and Shiznoka. Of these forty-five patients have died, and it is doubtful if some of the remaining ten will survive. Yersin's serum has been tried, but has not yet given evidence of a satisfactory nature as to its real value in the present appearance of the disease, which attacks and destroys the victim so quickly as to leave little time following its discovery for any measures whatever. It is said that the serum would doubtless prove useful as a preventive, if those exposed to contagion always made use of it. Three physicians have already contracted the disease while engaged in inspection, and died; while the wives of all three have likewise become infected, and may not survive. The infection is supposed to have been important from New-chwang, China, or Formosa, in which latter place it has existed for over a year, but in a far more malignant type than that of the disease now existing in Japan.

High fever, acute pneumonic symptoms, dyspnœa, and heart failure characterize the present appearance of the disease, which, it is thought by some, is carried in the air like influenza, an epidemic of which is now in progress.

Extensive and thorough sanitary measures are now being carried out, by which the examination of dwellings and the persons of the inhabitants of the lower class in cities threatened, and the complete isolation of patients suffering from the disease, or suspected of having it, are being accomplished; while special precautions are being taken upon all lines of travel for the inspection and detention when necessary of all suspects. These measures are being conducted under the supervision of Drs. Kitasato, Ogata, Nakahama, Shiga, and others, while Drs. Eldridge, Wheeler, and Koch, of Yokohama, are acting as an advisory committee in that port, where most of the foreign travel concentrates.

Dr. Eldridge, who as United States medical inspector has charge of the inspection of passengers proceeding on vessels to the United States, regards the outlook as serious, and considers most rigorous quarantine of new cases absolutely necessary, including the destruction of the buildings by fire when circumstances will permit.

In Tōkyō a wholesale cleansing has been going on for several weeks, including the taking up of floors and sweeping the ground underneath, as well as ceilings, when practicable. A price, 5 sen apiece (2½ cents), has been set upon rats and mice by the municipal authorities, and it is hoped that a general destruction of this kind of vermin will ensue.

The writer has driven rats out of his own house for a time by the use of a formaldehyde generator, placed between ceiling and floor, and phosphorus paste has also proved successful here, although neither of these means is applicable to the dwellings of the lower class in Tōkyō and other large cities in Japan.

THE APPENDICITIS QUESTION.

To the Editor of the Medical Record.

Sir: In the Medical Record for January 27, 1900, Dr. Morris asks if I know of any responsible surgeon who will operate for removal of the normal appendix. I do not, and I hope I never shall; but the logic of Dr. Morris' position must inevitably carry him to that very thing. It is only a step from operating on a very mild case because it is liable to become severe, to operating on a normal appendix because it is liable to become infected. If the doctor will divest himself of the glamour of hospital statistics, and put himself in touch with the sentiment of general practitioners and conservative surgeons, he will find that the appendicitis question is not an unending controversy, but that the great majority have practically settled the question of management in general, as follows:

"Operate as a rule in recurring cases. Operate in primary cases when circumstances arise which, in the opinion of the physician, make it justifiable."

There it is in a nutshell, as it were. Physicians might well wish it otherwise. What a weight of responsibility and care would be lifted from them, and how gladly would they adopt the exclusively surgical plan of operating on every case, if they could do so with justice and safety to their patients! Then it would simply be a matter of diagnosis, operation, and either recovery or leaving it to the surgeon to explain to the family how it happened; no worry, no responsibility, no drawing on the utmost resources of one's mind, that the best interests of his patients may be conserved. Yes, we would gladly adopt the surgical method, if we could honestly.

But again, if we would adopt the exclusively surgical plan, there is a practical obstacle to operating on very mild cases that would have to be overcome, that one in Dr. Morris' position is apt to lose sight of. A physician on reading the "Treatment of Appendicitis from a Surgical Standpoint" decides to follow it in his next case. He is called to see a patient supposed to be suffering from indigestion—belly-ache, or some kindred ill—and finds on careful examination that the patient has appendicitis. Although everything is apparently favorable for a mild attack, with every prospect of recovery, he calls the family and friends together, and tells them that the patient must immediately be cut open, and his appendix removed. They at once say to him, "Do you think he will die without operation?" and the physician, if honest, will answer, "No; the chances are ninety-nine out of one hundred that he will recover." "Then why do you advise operation?" they ask. He replies that something might come up in a few days that might alter the patient's condition, and make an operation advisable. Then he is met with the question, "Do you think there will anything arise?" and again, if he is honest, he will say, "There is a possibility that there may, but the chances are that there will not"; upon which they naturally wonder why it would not be advisable under the circumstances to wait until there was some sign of something unfavorable liable to set in in the case, before subjecting him to a serious operation. Then what will the physician do—insist upon an operation, and, if it is refused, retire from the case, because some surgeon high in the profession has said that every case, even if it were very mild, should be operated on? Or will he go on and treat the case in the manner which his judgment, based upon experience, and observation, and the accumulated experience of almost the entire medical profession, tells him to do?

There has as yet been no reason of sufficient importance presented to the profession why such a case should be operated on. "Sufficient unto the day is the evil thereof" is just as sound logic to-day as it ever was.

Dr. Morris says he has published letters from patients approving his method of treatment, and insists that we should be impressed by them: I am sure if the doctor would consider for a moment the thousands of letters published from patients testifying to the superiority of certain methods of treatment from cancers cured without knife or pain, to cases of locomotor ataxia cured almost while you wait, he would not lay so much stress on published letters.

Another point that Dr. Morris lays too much stress upon is the difference in the prognosis of cases treated medically and those surgically treated. He says we must tell the patient at the commencement of each case whether it is to be a mild or severe attack, or own up that the nature of each case is determined afterward. That saying would apply with equal force also in typhoid fever, pneumonia, scarlet fever, and many other diseases of which, of course, the positive outcome can be determined only afterward; but it is necessary for the successful physician to be able to make a prognosis beforehand, and it is certainly a matter of common knowledge that in any of the above diseases the physician will be asked immediately upon his diagnosis for a prognosis; and there are a certain group of symptoms taken together by which the physician is enabled to tell the patient's family, of course not positively, but very nearly so, that such and such a patient will recover unless complications set in; that another patient's chances are against him, and if it be appendicitis the experienced physician will be able to say with reasonable correctness that he will recover, or perhaps that his condition shows that an operation would give him a better show, or may be that he will probably die, but an operation may possibly save him, the prognosis depending upon the case and the circumstances. Now let us see what the surgeon would say. If it be a mild case and circumstances warrant, he can say that "an operation will probably result in recovery." I do not understand that Dr. Morris or any other responsible surgeon guarantees recovery in every case, even in operations on the mildest. If it be a primary case and complicated before the surgeon sees it, he will probably give a prognosis that is indicated by the gravity of the case. Therefore we see that the exact outcome can be determined only afterward in surgical as well as medical cases; as neither the physician nor the surgeon can guarantee recovery in a mild case, the relative value of their respective prognoses can be determined only by the results of similar cases in the past. In addition let us remember that the physician who has diagnosed a case of appendicitis, and has been enabled from the conditions to give a favorable prognosis, has in reserve the knife as a sheet-anchor, providing something does turn up to alter his first opinion.

Dr. Morris admits that he draws his conclusions from a careful comparison between the results of surgical and the medical treatment, as shown by hospital statistics. To show how unreliable and worthless to the profession such conclusions must be, we need only remind the doctor that the general practitioner does not employ the exclusively medical treatment, but also that hospital medical statistics show an immensely heavier rate of mortality than physicians find in their private practice. The uselessness of hospital medical statistics to the profession at large has already been published.

That Dr. Morris will never see the mode of treatment he upholds accepted by the profession at large I am confident, not only on account of any unsoundness which may exist therein, but also because it is essentially impracticable.

J. S. Horner, M.D.

West Pawlet, Vt., February 3, 1900.

OSTEOPATHY AND THE LAW.

To the Editor of the Medical Record.

Sir: Your editorial in the Medical Record of January 20th, on "The Set-Back for Osteopathy in Kentucky," ought to be a source of satisfaction to every one who has at heart the welfare of his fellow-citizens, not to mention the interests of the medical fraternity. That osteopathy unrestrained is not a harmless form of charlatanism, but a real menace to the life of many a poor patient, I have long been satisfied, and I wish to relate a case in point that a few weeks since drove conviction home to me more strongly than ever.

Called in great haste one morning to see a sick person in my neighborhood, I found a young woman dying in collapse—pulseless at the wrist; shallow, rapid respiration; ashen pallor, blue lips, pinched nose, clammy sweat; heart sounds feeble and very rapid, and temperature subnormal—but withal clear-minded. There was no pain, but profound weakness. She had had intense abdominal pain, especially in the right iliac region, since ten o'clock the previous day, but it had suddenly left her at about one o'clock in the night. Examination showed the abdomen moderately distended, tympanitic, quite rigid, and very sensitive, with marked resistance over the McBurney region. My diagnosis was ruptured abdominal abscess, probably appendical. In about five minutes after my arrival she lapsed into unconsciousness, and in ten minutes more was dead. Shortly before she died, another physician, summoned from a distance earlier in the day, arrived.

On inquiry of the friends as to the previous history of the case, I learned that she had for some days past complained of indefinite abdominal pains coming on at intervals, but had not taken to bed till the morning previous, and, indeed, had prepared breakfast for the family that day. Seized with severe pains about the middle of the morning, she went to bed, and had suffered intensely, vomiting several times, till the small hours of the following morning, when the pain suddenly subsided as I have said. I asked who was attending her, and was told she had had no physician, which I thought very strange, as they seemed intelligent people and were able to have one, and certainly her symptoms must have been alarming.

Returning to my office, I left affairs in the hands of the physician first called, as he was a friend of the family, and a little later was surprised to receive a call from him in company with the undertaker to get my signature on the death certificate. I did not see why he did not sign it himself, as he was quite as well qualified to do so as I, but he urged it, and I did so, and the body was immediately shipped out of town. The undertaker reported a discharge of pus through his needle when he inserted it to inject the peritoneal cavity, a confirmation of my diagnosis.

Later in the day I accidentally learned that the people in the flat where the young woman died were nearly all students of osteopathy, her own brother—who, by the way, is totally blind—being one of them, and that the president of the "college" had been called as soon as she had taken to her bed the day before. He had given her three "treatments" that day, and was in attendance upon her the morning of her death, and it was then at his suggestion that the physician had been sent for. I also learned that said physician—a graduate of Rush Medical College—is a teacher in the local "college of osteopathy" and is not infrequently called upon by osteopaths under similar circumstances (an osteopath cannot sign a death certificate here). Also, that upon being reproached one time by a former classmate for disgracing his profession by associating himself with charlatans, he replied in words to the effect that the profession might be ——, that he was out for money.

Being naturally indignant at the part I had been led to play in the affair, I resolved to find out if possible what diagnosis had been made, and what sort of treatment had been given, and accordingly called next morning on the president of the "college." He was nervous and fidgety when I mentioned the case, and spent some time assuring me that he would tell me exactly the conditions as he had found them. When he finally got down to business he stated that he found the patient had for some time been troubled with a little "stomach derangement" and "constipation," that the condition was somewhat exaggerated that day, but that she had presented "no alarming symptoms whatever," and he had assured the friends there was not the slightest cause for anxiety. Being asked what his diagnosis had been, he said he regarded her symptoms as due to a "posterior condition of the spine!" but did not deign to explain what that meant. Nothing could be learned about treatment, except that he had "treated" the lower end of the spine. Continuing, he said that when he visited her that morning he saw that "it was not a case for us to treat"—which meant he realized then that she was dying and that he might get into trouble, not being able to sign the death certificate—and so he had at once sent for the doctor before mentioned.

Since this episode I have taken the trouble to inform myself as fully as I could on osteopathy and osteopaths, visiting their "college," talking with devotees, reading their literature, and looking up their legal status here in Wisconsin. I have before me a copy of the *Wisconsin Osteopath*, a semi-occasional publication (price, $1 a year) which occupies the proud position of official organ to the "Wisconsin College of Osteopathy," and which at irregular intervals is left on our front doorsteps or tossed into our hallways. I quote briefly a part of the "farrago" of the osteopathic creed relative to the "spinal origin of disease," as set forth in its pages:

"Anatomists have discovered along the spine centres which control the various organs of the body, and in the development of osteopathy the whole system revolves to a certain extent about these centres, opening up great possibilities to the osteopath in overcoming disease. As before said, the nerves escape from the spinal cord through openings between bones, ligaments, and muscles with only a limited amount of space. The encroachment upon this space by the contraction of a muscle or the slipping of a bone may cause a disturbance in the organs of the body to which these nerves, with their sympathetic communications, pass. Upon these nerves the osteopathist must play, as upon the keyboard of a piano, removing any pressure or obstruction which would cause discord in the nerves, or in the functions of the organs which they supply. It is upon the spine, for this reason, that the osteopathist does the major portion of his work."

Could anything be more cunningly devised to catch the attention and appeal to the reason (?) of the average patient, who always wants to know the why and the how? That it does catch them is evident from the fact that the school has a large following both here in the city and all over the State, and it does a flourishing business in the turning out of new D. O.'s—Diplomates in Osteopathy—to catch the shekels of the unwary.

What is more surprising is that this official organ, distributed from house to house, contains in its reference column the names of some of our best-known citizens as indorsing osteopathy. They may have been benefited by their treatment—we all know that massage (or manipulation, as they prefer to call it) has a field of usefulness—but that they should be willing to have their names distributed about the town to advertise somebody else's business, is indeed astonishing. That is putting themselves in the same class as those who testify in the daily papers to the merits of "Lydia Pinkham," "Dr. Pierce," "Peru-na," etc.

To sum up the results of my investigations in brief: I find that the osteopathic principle of treatment is based on a substantial truth well recognized as valuable in certain conditions and long practised by the members of the regular profession, viz., digital manipulation of the body regions; that about this kernel of therapeutic truth they have constructed their "science," which to the laity appears most plausible, but to the enlightened is a meaningless mass of nonsense; that their etiology is mere fiction, their pathology a myth, diagnosis is a conjecture, and all are carefully planned to harmonize with and support their one uniform line of treatment. In other words, it is a made-to-order science. Their course of study in no way fits one for the intelligent care of the sick.

Now I am not opposed to specialties. We have specialists in all branches of our art, and if any one wishes to specialize in the treatment of proper cases by manipulation, well and good; but first make him comply with certain requirements of preparation, as all legitimate specialists are made to do, so that he will be presumably capable of selecting cases amenable to treatment by his methods—and then when he is found manipulating an appendical abscess or sticking his finger into a diphtheritic throat, let him feel the strong hand of the law, the same as any other malpractitioner. As matters stand now in most of our States, the osteopathists openly boast of treating anything and everything, advertise themselves as doctors, and yet are not amenable to law, because, forsooth, they do not give medicines, and so are not recognized and regulated. Is not this most unjust to the rest of us, as well as a menace to the public welfare?

PHILIP F. ROGERS, M.D.

MILWAUKEE, WIS.

SERO-THERAPY IN PNEUMONIA.

To the Editor of the Medical Record

SIR: Referring to the letter of Dr. Fanoni in the MEDICAL RECORD of January 27th, if Dr. Fanoni will consult the sixteenth volume of the "Twentieth Century Practice of Medicine," at pp. 122–129, he will be "really surprised" to find that I have discussed at considerable length the claims of sero-therapy in pneumonia.

ANDREW H. SMITH, M.D.

18 EAST FORTY-SIXTH STREET.

THE USE OF KOLA IN SEASICKNESS.

To the Editor of the Medical Record.

SIR: Some of your readers may be interested in my experience in the use of the kola nut for the amelioration of seasickness during the past fortnight in a voyage from Yokohama to San Francisco. The first five days of the trip were rough, the third being marked by a westerly gale. I am an indifferent sailor, and in such weather commonly find no little difficulty in doing my part in the care of a family of four small children. By keeping a piece of the dried nut in my pocket and frequently biting off a morsel to chew slowly I found myself free in the main from the swimming head and the sour stomach which would otherwise have attended the washing and dressing, the feeding, and other attentions necessarily rendered the little ones, who shared but slightly in my indisposition. If I waited till stomach symptoms appeared, no effect seemed to result from the use of the nut; probably because nausea and vomiting followed so rapidly as to forestall absorption. But when taken with a clear head and a sound stomach, as upon waking in the morning after a refreshing sleep, the effect seemed almost specific in preventing the severer symptoms of mal-de-mer. The effects are not immediate, but result in about twenty minutes or half an hour, and seem mainly to lie in the stimulation of the nervous system and the general toning up of relaxed tissues which are known to be the proper physiological effects of the drug. More especially did I note the freedom from bile among the stomach contents, even when the roughness of the sea and confinement to close cabins brought on fits of vomiting. The latter was mild in degree and accompanied by no retching or bitter taste. Moreover, at a later period of the voyage, with a much smoother sea, circumstances otherwise similar brought on repeated vomiting with deep retching and with the raising of bile and even of blood, soreness of the hypochondrium, lightness of the head, burning pain in the oculomotors, and all the other aggravating symptoms of seasickness.

I conclude that kola nut does not cure but decidedly ameliorates seasickness, if taken in time, through its familiar action as a cerebral stimulant.

C. C. VINTON, M.D.

SUCCUS CINERARIÆ MARITIMÆ IN CATARACT.

To the Editor of the Medical Record.

Sir: I read in the Medical Record of January 27th, p. 165, that the editor of *Experience* says: "The use of succus cinerariæ maritimæ, for the absorption of cataract, when dropped into the eye daily, two or three drops at a sitting, acts in many instances with results nothing short of miraculous."

Dr. Lewis F. Read, surgeon-general Pennsylvania National Guard, and myself used this remedy, as suggested, on the eyes of my mother, aged seventy-six years, a resident of Norristown, Pa., for eighteen months without any result whatever, except to give her needless pain.

Albert S. Ashmead, M.D.

New York.

OUR LONDON LETTER.

(From our Special Correspondent.)

WAR—INTESTINAL RESECTIONS—MASTOID OPERATIONS—SATURDAY HOSPITAL FUND—INFLUENZA—RECENT DEATHS.

London, February 2, 1900.

The medical world pursues its course amid the clash of arms, as in the times of peace. Every hour we are reminded that we are at war. Amid the curses, loud if not deep, which are being heaped on the War Office, it is cheering to find that even the "man in the street" has become aware that the doctors, at any rate, have not failed. Lord Methuen has said in a despatch that he was glad to have been slightly wounded, as in no other way could he have learned the care taken of the wounded, and how the medical officers never tired in their endeavors to alleviate the suffering. We may take this testimonial as a set-off against the spite of Lord Wolseley, who is now likely to have enough to do to defend himself against the charge of neglecting his obvious duty. The meeting of Parliament has already put the government and their experts on their defence. News from the front is continually coming to hand. Even the medical journals boast of their special correspondents in the field and at the several hospitals. Letters, too, are coming from Sir W. MacCormac and the other civil surgeons sent out by the War Office to disguise their own insufficient arrangements. But their letters can only describe the work of the army medical officers, to whom they give unstinted praise, and mention a few remarkable cases. It is too soon to expect much, but later on we may gather some valuable surgical lessons from the horrible conflict. I turn from it to the peaceful work we are engaged in at home.

At the Clinical Society on the 26th inst. Mr. Hutchinson, Jr., related two cases of resection of gangrenous intestine in cases of hernia. One was that of a woman with femoral hernia, five inches of intestine being removed, and the patient was found in good health six years afterward. The other was that of a man with strangulated inguinal hernia; ten inches were removed, and the patient recovered. He died three years afterward from ulcerative colitis, and Mr. Hutchinson obtained the specimens which he showed at the meeting. At the seat of resection, there was not the least narrowing. In both these operations suturing only was employed, and in reference to the relative safety of this plan and the use of Murphy's button, Mr. Hutchinson said he had collected from hospital statistics fifteen cases of primary resection for gangrenous intestine with the button and sixteen without. Of those with the button, only one patient recovered, or seven per cent.; of those without, six recovered, or forty per cent. Further, in the fatal cases sutured alone, the patients survived on an average twice as long as in the others. Three of the ten fatal cases simply sutured might have resulted in recovery but for complications—multiple strictures, obstruction by band, and phthisis. The post-mortem records showed, moreover, better union after simple suture. The longer time required for accurate suturing did not seem of great importance against the disadvantages of the button. It was necessary to excise enough to secure the sutures being inserted in healthy tissue, and it was generally advisable to do it through a median abdominal incision. If the intestine could be emptied and made to contract, this would favor union, and prevent infection of the stitch apertures by the contents. Possibly an aperient directly after the operation would improve results.

Mr. Barker preferred to dispense with the button, and insisted that the amount of intestine removed did not matter much; the one element of success was to place the sutures in healthy tissue, the walls of which had not been damaged by distention.

Mr. Marsh also insisted that no untrustworthy part should be included in the sutures.

Mr. Charters Symons was also against the button, and thought the great difficulty was to empty the bowel in order to prevent a continuance of the symptoms from its paralysis.

At the same meeting Mr. Gould read an account of the case of a man aged twenty years, who was accidentally shot in the abdomen with a small revolver. Seen an hour later, when he was partly under the influence of a morphine injection, the respiration was easy, and the pulse 96. There was still pain. The wound was found to extend into the peritoneal cavity; it was freely opened, and blood flowed out, but no gas or bowel contents. Four wounds were found in the jejunum, three perforating. They were closed with Halsted's sutures of sterilized silk. Two wounds of the mesentery close by were also sutured. The peritoneal cavity was cleansed, the bowel returned, and the abdominal wound closed. The man recovered. The bullet was located in the left buttock and was let alone. Mr. Gould approved the injection of morphine, as it relieved pain and shock and intestinal movements, thus lessening the chance of fouling the peritoneum. He thought the case showed the value of careful exploration in perforating wounds of the abdomen.

Other speakers concurred in the value of morphine, which some thought too much neglected at the present time. It was also agreed that exploration was desirable, when it could be done under favorable circumstances; if the patient was not seen until after the lapse of a long time it might be doubtful, and a recently reported case was referred to in which a bullet passed through the abdomen, and the man recovered though nothing was done. Saline injections were mentioned as useful for overcoming shock in some of these cases.

Three communications in one evening on such a subject as the mastoid operation make a full dose for even so grave and staid a society as the Royal Medical and Chirurgical, and not unnaturally led to an adjournment of the discussion to which the contributions are expected to give rise. Such was the course of events at the last meeting (January 23d).

Mr. Ballance opened the evening with an account of twenty cases on which he had operated, and six of his patients were shown. He advocated the treatment of intractable otorrhœa by two distinct operations. The first of these is the complete mastoid operation to get rid of the disease; the second is directed to the healing of the wound by epithelial grafting of the raw bone cavity. He noticed the difficulty of selecting cases for the mastoid operation, and thought clinical experience a safer guide than rigid rules. But the cases being suitable, he would certainly follow on with the grafting.

Sir William Dalby followed with a paper dealing chiefly with the selection of cases for operation. He said it was necessary (1) when septicæmia had begun; (2) when there was carious bone in the tympanic cavity, with ominous symptoms often recurring; (3) when there was evidently mastoid disease. On the other hand the question of operation was often one of doubt, even when dead bone was present, but without ominous symptoms. Cases also occurred in which a less complete operation might be done. It should not be forgotten that many persons went through long lives with perforations which at times discharged slightly, but at other times were dry and apparently healed, and that, too, without experiencing discomfort enough to make them desire active treatment. They could hear pretty well, and transact the ordinary business of life, and only of late had it been suggested to adopt severe measures in such cases.

The third communication was by Mr. Cumberbatch, who thought it was easier now than formerly to decide on the cases suitable for operation. First he specified three groups of cases, in which, speaking generally, he did not adviseo peration; *i.e.*, (1) when the whole or the greater part of the membrana tympani was destroyed, and the mucous lining of the cavity hypertrophied, but without bone disease; (2) when there was frequent discharge for a time, but easily arrested, the perforation being permanent or else closing on the cessation of each discharge; (3) when both ears were discharging, but the hearing remained good, and there were no symptoms calling for interference except the discharge. On the other hand, he specified four groups of cases in which the complete mastoid operation was advisable, viz.: (1) In recurrent discharges when every onset was preceded by malaise, headache, and rise of temperature with sometimes mastoid tenderness; (2) in "spoilt ears," which, after giving no trouble for years, suddenly developed symptoms of labyrinthine vertigo, showing that inflammation was involving the labyrinth, or some accumulation was causing pressure; (3) intermittent discharges with masses of sodden epidermis, often hiding small granulations, and when syringing constantly removed white shreddy patches, the usual treatment having failed; (4) periodical attacks of mastoid pain after active mischief had ceased in the ear, and when neuralgia could be excluded.

The Hospital Saturday Fund decided last week to distribute £17,013 13*s.* 8*d.* among the hospitals, dispensaries, convalescent homes, and auxiliary organizations, such as ambulance, surgical appliance societies, and institutions for the gratuitous nursing of the sick poor in their own homes. The gross income of the fund for 1899 was £20,023 5*s.* 3*d.*

Influenza is still decreasing. The deaths registered last week from this disease numbered one hundred and fifty-two as against two hundred and eight in the previous week. The average death rate in England and Wales was 22.6, as against 24.9, 29.1, and 30.9 in the preceding weeks, a steady fall chiefly due to the decline of the epidemic. Turning to the provinces, Birmingham is suffering from influenza and typhoid. At the same time whooping-cough and measles are so prevalent that the work of the schools is much interfered with. No less than one hundred and eighty-seven fresh cases of measles and seventy of whooping-cough were reported among the children attending the board schools last week. In most of the other great towns which have been attacked by influenza, there is an abatement of the disease, varying in degree with the date of its appearance.

Mr. Bernard Brodhurst died on the 30th ult., in his seventy-eighth year. He was for many years surgeon to St. George's and the Royal Orthopædic hospitals and published lectures on orthopædic surgery and other works.

Sir William Miller, J.P., M.D., of Londonderry, died on the 28th ult., aged seventy-three years. For more than forty years he held a most prominent social and professional position in his native city, where his father had had a similar position, being M.D. and J.P., and dying at the great age of ninety-two years. One of Sir William's sons is also in the profession.

Dr. T. J. Dyke, J.P., died on the 20th ult., aged eighty-four years. He was for over thirty-six years medical officer of health for Merthyr.

Another J.P. and M.O.H. was Dr. H. H. Vernon, of Southport, where he settled some thirty years ago. He died on the 16th ult., aged sixty-nine years.

Surgeon-Major A. C. A. Alexander of the Coldstream Guards died on the 23d. He served with his regiment in the Sudan, and last year had a sunstroke at Gibraltar, and regretted not to be able to go to South Africa.

New Instruments.

A RECTO-GENITAL IRRIGATING TUBE.

By RAMON GUITÉRAS, M.D.,

NEW YORK.

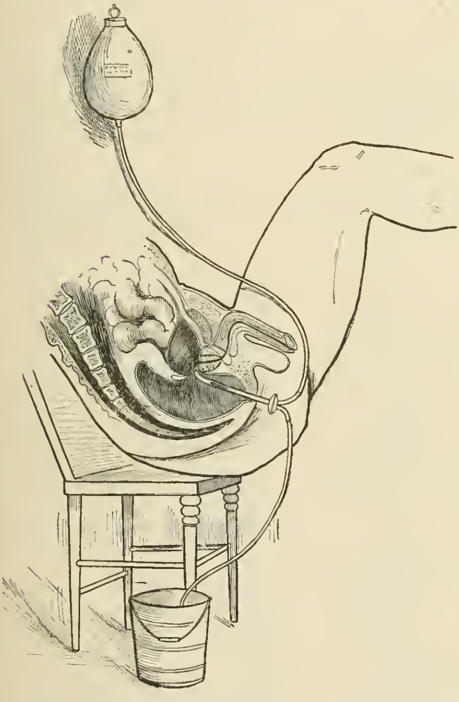
The tube under consideration is called the "recto-genital irrigating tube," because it is one which, although inserted in the rectum, is intended for the treatment of diseases of the internal genitals, and not for those of the rectum proper. The diseases of the internal genitals for which it is used are those of the prostate gland and seminal vesicles, and embrace acute and chronic seminal vesiculitis, acute and chronic prostatitis, prostatic abscess, acute inflammatory attacks occurring in cases of prostatic hypertrophy and certain functional disorders, as prostatorrhœa, spermatorrhœa, and atonic impotence.

Description of the tube: The tube is six inches long and one-half an inch in diameter. It is slightly curved at the end for insertion, thus presenting a convex and a concave surface, the latter better accommodating itself to the internal genitals, particularly the prostate. There are three openings near the end of the tube, one in the concavity and one on either side of the straight part of the shank. At the other end, the one which may be called the proximal, there is a shield with two pipes protruding from it, one of which connects by means of a piece of piping with a reservoir on the wall, and the other, or waste pipe, connecting with a receptacle upon the floor. The tube is so constructed that it is double throughout its entirety. The irrigating fluid comes down from the receptacle, generally a douche bag hung on the wall, enters the tube by means of a piece of tubing, and passes along the upper compartment, escaping through the opening in its concavity, and bathing the parts to be treated, the seminal vesicles or prostate. It then again enters the tube through the two openings in the sides and escapes by means of the attached tubing into a receptacle on the floor.

The opening in the concavity by which the fluid enters the intestine is smaller than the side openings through which it escapes, thus rendering the outflow more than twice as great as the inflow, and in this way overcoming the great difficulty which is usually encountered in rectal douches, namely, the over-accumulation of the fluid in the gut. The opening in the concavity also presents a decided advantage over one in the end, where it is usually situated, as the tube, being smooth at the extremity, enters more freely, and also because the fluid is discharged directly against the internal genitals instead of shooting by them up the rectum.

The material used for making the tube is generally hard-rubber or metal; the former is more liable to be injured and is not so easy to clean and sterilize as the latter.

Description of fluids: The fluids used are generally hot salt solution, or flaxseed tea. The former is made by adding a teaspoonful of salt to a quart of water, the latter by adding a tablespoonful of flaxseed meal to a quart of water, boiling and straining. Plain hot water seems to dry the parts, and is much inferior in its effects. The temperature of the fluid is generally from 105° to 120° F., a good rule being to use the water at the temperature which gives the most relief and produces the best results.



The technique of a rectal irrigation is as follows: The patient should assume a reclining position with the legs elevated. If he lies in the bath tub with his feet elevated on its sides, or if he reclines in a chair with his legs up, he is in a good position to receive an irrigation. The douche bag should be hung so that its bottom is just above the head of the patient, which will admit of an easy refilling if necessary, although it should be placed still higher in case the pressure of the fluid is not sufficient to allow it to make the circuit freely.

The tube should be lubricated, and inserted with a rotary movement. If the case be a prostatic one, two and three-fourths inches is sufficiently far, while if it be a disease of the seminal vesicles it should be pushed up from three and one-half to four inches. From one to four quarts of fluid should be used at each sitting. The best time for taking the irrigations is just before retiring. If the fluid is not escaping freely, and too much has accumulated in the intestine, the inflow tubing should be compressed until some of the fluid already in the gut has escaped. If the fluid does not escape freely, the tube should be moved about in the rectum until a better flow is established.

The diseases for which this method of treatment is generally used have already been enumerated. The benefit is derived from the effect of moist heat. In the case of acute prostatitis it gives great relief to the pain and at the same time diminishes the inflammation. In cases of prostatic abscess it stimulates the circulation in the gland, thus hastening either absorption or suppuration. In diseases of the seminal vesicles it also reduces the inflammation by the action of the heat, as is evident by the diminution of the pain and tenderness at each rectal examination. In prostatorrhœa it relieves any deep irritation of the genitals, upon which the relaxation may depend. In cases of atonic impotence the cause is often a chronic inflammation of the vesicles, which is benefited by the irrigation.

In almost all these cases amelioration is hastened by gentle massage of the internal genitals per rectum every four or five days. This not only tends to cause absorption of any inflammatory exudate, but it breaks up adhesions and strengthens the function of the prostate or vesicles.

When the inflammation has left the part, as is evidenced by the absence of tenderness on rectal pressure, then hot irrigations are of no further use, and can be discontinued, or if the parts are relaxed the tone may often be better restored by general tonics, the use of cold water by means of the recto-genital psychrophore, or by electricity administered through a rectal electrode. A recto-genital psychrophore is of the same shape and size as the tube under consideration, although it has no opening in its shank. The cold water simply circulates through the tube, thus applying constant cold to the parts.

63 West Fifty-fourth Street.

Medical Items.

The Influence on Health of Chemical Preservatives in Food.—As a result of an experimental investigation, Foulerton (*Lancet*, December 9, 1899) expresses the opinion that it is extremely improbable that boric acid or formic aldehyde, used in small proportions for the preservation of milk, would cause any injurious effect whatever to the average adult taking the ordinary amount of milk with his daily food; but because of certain possible injurious effects that might result, the use of such preserved milk for invalids and young children taking large quantities is to be condemned. So far as these injurious effects are concerned, it appears unlikely that the digestive processes would be materially affected—or, indeed, affected at all—by the boric acid, but that toxic effects in a more general way might be produced by this preservative. Formic aldehyde, on the other hand, would probably have no injurious general effect in small proportions, but would tend to lessen somewhat the digestibility of the milk. The necessity for legislation on this subject lies in the fact that these preservatives are, in small proportions, tasteless and so cannot be detected by the consumer. Such legislation should provide that no preservative should be used that is not sanctioned by the proper authority, and that the proportion should not exceed a certain maximum amount to be fixed officially; that the nature of the milk should be declared by the vender, and that it should be sold only as "preserved milk." The penalties for infringement of the law should be sufficiently heavy to render un-profitable the sale of "preserved milk" as fresh milk. There is no good reason for the presence of salicylic acid or other special preservative in such articles of food as jam, cheese, and pickles, while the use of certain preservatives as substitutes for alcohol is a matter of fraud pure and simple. The use of a tasteless preservative in butter must also be regarded as fraudulent unless the fact is declared. The use of boric acid for salting bacon and ham may or may not cause injury to the consumer, but such articles should not be sold with concealment of the fact.

Erythromelalgia.—Rosen (*Berliner klinische Wochenschrift*, December 4, 1899, p. 1081) reports a case of erythromelalgia in a demented individual, and from a study of the literature expresses the opinion that in the majority of cases of this disease the symptoms are dependent upon a lesion of the central nervous system. A number are in fact attended with symptoms of such lesions, and upon which the erythromelalgia may be considered as dependent. In another group of cases, however, there is no manifest organic lesion of the central nervous system, but in these also the disease, in its localization, in its course, in its association with various sensory and trophic disturbances, and in its combination with certain general manifestations, is suggestive of a disorder of the central nervous system.

Acute Acquired Internal (Idiopathic) Hydrocephalus.—Heidenhain (*Berliner klinische Wochenschrift*, December 4, 1899, p. 1078), upon the basis of four cases carefully studied and from an analysis of the literature, expresses the opinion that acquired idiopathic internal hydrocephalus is a disease *sui generis*. It may set in abruptly (serous apoplexy), or it may develop insidiously. Under the conditions first named, recovery may take place, while under the latter the disorder is probably incurable. The insidious variety either pursues an even course or is interrupted by exacerbations. These are characterized by sudden depression of temperature and of pulse far below the normal, with increasing restlessness. Death occurs with gradual perversion of consciousness in consequence of asthenia or intercurrent disease (pneumonia, severe digestive disturbances, etc.). With regard to the etiology, direct injury to the brain is not essential to the development of acquired idiopathic internal hydrocephalus. The disease is caused by cold, and must be considered a vasomotor reflex neurosis. With regard to the acute exacerbations these may be explained by the limitation of the serous effusion by the resistance of the elastic brain. If this subsides in the course of days or hours, a new effusion takes place, and this again is restricted by the limits of compressibility of the brain. The assumption that the brain first undergoes atrophy and that the effusion occurs at the same time in consequence of the rarefaction, is absolutely incorrect. The high degree of pressure under which the exudate exists is opposed to this view. In one of the cases recovery was observed in the sequence of subcutaneous injections of morphine, which not only induced rest and sleep, but allayed the vasomotor spasm. In the insidious cases persistent treatment with subcutaneous injections of morphine or suppositories of codeine may be recommended.

An Electric Danger for Horses.—Herr Rusterholz, writing to the *Schweizer Archiv* and reported in *The Veterinary Journal*, relates a somewhat startling story which may put veterinary surgeons on their guard in these days when electricity is used everywhere. He says that two carriage horses got into the habit of refusing to take their oats. They both appeared to be in perfect health, ate hay with appetite, and took their oats easily; but at a given moment after they had consumed a part of their ration, they tried to take up the oats at the bottom of their iron manger and suddenly recoiled, making curious movements with their heads. The animals did their work well and seemed to be in good spirits, but the same strange conduct was repeated at each meal. When Rusterholz was called in he began by examining all the food, especially their oats. All was found to be of excellent quality. Wishing to see if the oats lying in the manger had not undergone some deterioration which might explain the symptoms, he thrust his hand into the oats, which were now somewhat moist by admixture with saliva and water. Each time he did this he felt a curious tingling, such as is produced by an electric current. The stable being lighted by electricity, Rusterholz caused the wires to be examined, and this brought about the discovery that over the horses' heads the wire had become denuded of its insulating cover; the current was transmitted by the coat of paint, which had become an excellent conductor by reason of a slight coating of moisture deposited on its surface through the condensation of vapor, and this current reached the iron manger. It did not cause the animals any trouble so long as the oats were dry; but as soon as they became damp by the saliva and condensed vapor from the horses' breath it took effect, and the animals were subjected to it every time they took a mouthful of oats.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended February 16, 1900:

		Cases.	Deaths.

SPINAL FRACTURE—PARAPLEGIA.[1]

BY ROBERT ABBE, M.D.,

SURGEON TO ST. LUKE'S HOSPITAL, ETC.

THE subject on which I have been asked to make some remarks to-night is one that interests not only the surgeon but the physician, because of the certainty that every physician may, sooner or later, be brought face to face with this distressing accident of a broken neck, or of a broken back, in the person of patient or friend.

One sees children fall in climbing trees, or from swings, or over banisters; youths suffer broken necks in diving, workmen falling from scaffolding, elevator accidents, falling from cars or out of carriages, horseback falls; and in all cases the sudden, horrible, and instantaneous paralysis of the body faces the physician, and it is of the greatest moment to him that he should be able to say to the distressed family what the probable future will be, and what can be done at the moment or in the future. Life-long paralysis will inevitably follow the accident in perhaps the great majority of cases in spite of all care, because the accident, as we shall see presently, produces a fracture of the bodies of one or two vertebræ, with instant dislocation and crushing pressure upon the soft spinal cord.

In many cases, after the damage, the displacement is spontaneously corrected in part by the rebound of the body to its natural position, so that after being damaged the cord is not compressed within the canal, but in most cases the sharp angular deformity within the canal produced by the impaction of the fractured vertebræ holds the spinal cord tightly squeezed against the posterior laminæ. In these cases there is less chance for restoration of the damaged cord after nature has absorbed the temporary hemorrhagic pressure.

It is from a rather large experience in cases of broken neck and broken back, including two gunshot paraplegias also, that I venture to speak of the following points.

Let us group the cases one sees according to symptoms with which the physician should be familiar, and note the correspondence between the early symptoms of damaged cord and the intensity of the damage. Before studying these let us note one condition allied to and simulating broken neck which stands out in bold relief and should be ever present in the mind of the physician; that is, "dislocation of the neck."

I am able to show to-night a good radiograph illustrating for the first time the real deformity (Fig. 1). It has been supposed, heretofore, in the absence of post-mortem opportunities, because the cases are almost never fatal, that the characteristic deformity of dislocated neck is due to the displacement of one articular facet backward into the notch on the upper side of the vertebra below, thus giving the peculiar cock of the head and slight rotation of the face to the affected side.

The case in which this radiograph was taken is of a boy aged nine years, who fell down one flight of stairs last July, and instantly his head was fixed immovably in the characteristic position; there were little pain and no paralysis. The radiograph shows a dislocation of the axis upon the atlas of one side.

The deformity has usually been imagined to exist between the middle cervical vertebræ, but in both lateral and front views of this case these vertebræ are clearly seen to be in their normal relations.

It is of interest in this case that the reduction was spontaneously accomplished during sleep the second night after the accident; the boy awakening to find his neck perfectly supple and correct. The explanation is readily seen: the muscular relaxation during sleep, with the leverage afforded by the patient's restless movement on the pillow, accomplished what would have been done under ether and by surgical manipulation.

To grasp more easily the relations between the damage in broken-neck cases and the group of symptoms following, let me illustrate this large and varied class of accidents by three cases of broken neck from diving, which have come under my observation this last year.

CASE I.—A man, aged twenty-eight years, was diving in shallow water, sandy bottom; he suffered instantaneous paralysis below the neck; he was rescued quickly and found to be unable to move the muscles of the body, but on examination directly after it was found that there was slight voluntary motion of the limbs and only partial loss of sensation. Soon after the accident the predominant symptom was increasing and incessant jactitation of all the limbs, which did not subside for some days. After the third day better voluntary action ensued, numbness diminished, and in three weeks the patient had excellent control of all his muscles.

CASE II.—Boy, aged nineteen years: he was diving in shallow water with sandy bottom and struck his forehead; he instantly realized inability to move anything below his neck. Consciousness was perfect. He noticed a flapping motion of the limbs in the water, and held his breath until rescued. He was absolutely paralyzed below his neck for three days. Sensation was almost entirely lost, but he could feel pin-pricks at some points; the arms also had a prickling sensation as if asleep. After two days he could move the tips of the fingers and draw up the left leg, and could bear his weight on one leg in two weeks, and in three weeks could walk. He made a rapid convalescence. Six months from the accident, there remains some wrist-drop of the right hand, feeble grasp still improving, but otherwise nearly normal. The case might well have been regarded as one of hemorrhage only, within the vertebral canal, with very slight damage of the cord; no deformity of the spine could be discerned either in the pharynx or by external palpation. It remained, however, for the radiograph, which I show here, to show a most perfect comminuted fracture of the body of the fifth cervical, which is clearly shown to be crushed into a wedge instead of a square shape. The displacement forward of the upper segment is less than usual in these cases, and explains graphically why the cord was contused rather than crushed, and hence the transient paralytic symptoms.

---

[1] Read before the Practitioners' Society, December 5, 1899.

Case III.—A young athlete and skilful swimmer was diving in three feet of water; his forehead struck the sand, the head being thrown forward with chin upon the sternum. Immediately instant paralysis ensued. Consciousness was retained. He held his breath until rescued. He was seen by me two hours afterward. I found motor paralysis absolute below the neck, except for the fifth root group of the shoulder, viz., deltoid, brachialis anticus, and triceps, giving the arms the characteristic position, elbows held out from the sides, hands resting on pectorals. Respiration was entirely by the diaphragm. To my surprise the skin was sensitive over most of the body, even down to the feet, and the patient had made voluntary flexion of two middle toes of the right foot. The head, neck, and chest were encased in a plaster-of-Paris support, traction of the spine being maintained during hardening to correct the deformity as much as possible. Two unusual features in this case justified a shade of hope in an otherwise unpromising outlook, viz., the apparent, slight, voluntary action in the right foot, and the retained sense of touch over the body; both arguing an incomplete destruction of the cord. A successful radiograph was taken promptly, showing a comminuted fracture of the body of the fifth vertebra. The posterior bony wall of the canal, marked by the laminæ, was apparently nearly flat. The alignment of the spinous processes also seemed nearly normal, from which it appeared that the cord remained under pressure, which the removal of the posterior wall (laminæ and spine) would relieve. The patient urgently desired an operation at the earliest possible moment; but it was not until the fifth week that any interference could be tolerated. Meanwhile, evidences of local myelitis and meningitis ensued—namely, a severe girdle pain at the limit of anæsthesia, jactitation of the lowest unaffected muscles, and loss of any muscle action below.

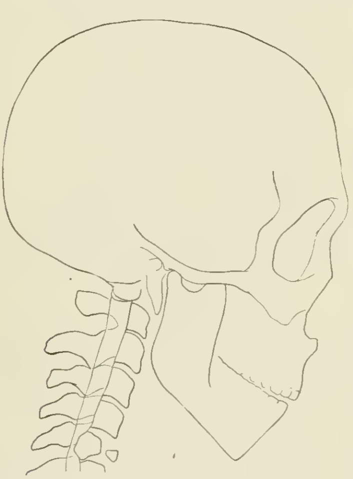

Fig. 1.

Cutaneous sensation with thermal sense was carefully noted by Dr. Pearce Bailey from day to day, who found but little change. After the second day, however, acute pulmonary œdema with rusty expectoration and hypostatic pneumonia (temperature, 104° F.) prevented any operative interference.

The temperature during five weeks after the accident varied from 101° to 103° F., with exacerbations due apparently, in some instances at least, to intestinal putrefactive changes relieved promptly by calomel purge. The patient wasted much during his confinement.

Operation six weeks after accident: cutaneous and deep muscular anæsthesia by cocaine (fifteen drops two-per-cent. solution) was resorted to, general anæsthesia being impossible on account of diaphragmatic respiration. The laminæ of the fifth vertebra were found fractured, close to the transverse processes on either side, and removed with the greater portion of the lamina of the sixth also, and the spinous processes all but the tips. The underlying dura was found of a deep mahogany red and exquisitely sensitive to the pressure of a sponge, and rounded up into a full, soft swelling immediately upon removal of the flat bony pressure. The acute sensitiveness of the dura to the slightest touch was most interesting evidence of the local meningitis, and corroborates what I have noticed before in serous membranes, that, when uninflamed, there is no pain sense, but when inflammation sets in the pain on handling is very acute.

Owing to the opportunities afforded by cocaine operations, one may occasionally compare the uninflamed dura mater, knee joint serous surfaces, and peritoneum with the same membranes when inflamed, and find that these membranes are absolutely free from pain-sense when handled in the uninflamed condition, but that the slightest touch in the inflamed condition elicits a cry of pain from the patient.

The cord being thus relieved of all posterior pressure, the wound was closed, and the patient felt no ill effects from the operative procedure.

On the third day after operation the temperature declined to nearly normal for the first time since the accident, and continued until in another week it was running normal morning and evening. The girdle pains progressively diminished and soon entirely disappeared. The general cutaneous circulation continued to improve, so that the nurses volunteered the statement that pressure points required less care to maintain good circulation. General nutrition improved and the extremities seemed warmer. The patient soon became entirely free from muscular jerkings of the arm and chest muscles. Frequent rigors, to which the patient had been subject, and which were independent of much temperature elevation, but which always called for blanketing and hot bottles, now ceased. The posterior splint upon the neck was removed eight weeks from the time of accident, the bony spine being then well united. He soon regained full and painless use of his neck.

Twelve weeks from the time of accident the patient was allowed to sit up in bed, and one week later was allowed exercise in a wheel-chair in the upright posture.

At the end of the sixth month from the accident the patient's condition is as follows: Sensation is almost complete over the entire body, being restored in some anæsthetic areas which were present after the accident upon the lower extremities. Sensation in the left little finger, absent after the accident, returned after four months. No voluntary motion has yet returned in the paralyzed muscles. The power of motion in the upper extremities has steadily increased, so that the patient can now raise his hands to his face and forehead. This seems rather due to better voluntary control and coordination of the lowest group of unparalyzed muscles.

Dr. Pearce Bailey, examining the patient at the expiration of six months, reports: "The improvement in his condition is most gratifying. With the exception of the anterior tibial groups, all the muscles respond to faradism. This is true not only for those in which voluntary motor power has returned, but also for those which are still totally paralyzed. This persistence of faradic irritability is a reliable indication that muscles which are now partially useful will become more so, and that there will ultimately be some return of power to those which are still powerless. Thus, I think we have strong reason to hope that in the upper extremity the deltoid, the biceps, and the extensors of the wrist and fingers will get steadily stronger, and that in time the triceps, the flexors of the wrist and fingers, and the intrinsic muscles of the hand will undergo some restoration of function. The same holds good for the muscles of the thigh. The anterior tibial group of muscles do not respond to the faradic current, the current, when applied to this region, passing through and causing a contraction of the posterior groups. While this cannot be construed as a positive indication that these muscles will remain totally and permanently paralyzed, it is certain that if power returns to them it will be at a much later date than to those which respond to faradism."

The patient's general health is otherwise restored. The temperature has been continuously normal. The diaphragm has accustomed itself to the perfect management of respiration. Nutrition is good, so that he has reached almost normal weight. The digestive functions are perfect. The patient sleeps regularly and without pain; he sits upright in a wheel-chair two to four hours daily, having perfect control of his head, and using his neck naturally without apparatus.

We see in this case a more hopeful condition than when the complete crushing of the cord is shown by symptoms of complete sensory and motor anæsthesia and absence of knee jerk. In the latter case there is usually a sequel of symptoms which tend to exhaust the patient and end life within a few weeks, viz., pain, distributed on the border line of anæsthesia and at the site of fracture, requiring morphine sooner or later in considerable doses; cellular œdema of the extremities, bed sores, and cystitis; pulmonary engorgements and intestinal disturbances.

The combination of symptoms, sensory and motor paralysis with loss of knee jerk, is not necessarily a hopeless one, as is shown by the following interesting case:

Case IV.—E. M——, a stout muscular man, aged thirty-five years, war correspondent in Cuba, was shot by a Spanish Mauser bullet over the second left sacral vertebra and was instantly paralyzed below the hips. Two months afterward he came under my care, still suffering complete sensory and motor paralysis of both extremities and loss of knee jerk. An *x*-ray photograph showed the bullet at the site of the right renal vessels; to have traversed this course it must have ascended alongside the lumbar vertebræ and deflected across the first lumbar. Examination by Dr. Pearce Bailey established the lower segment of the cord as the part injured. I operated, removing the laminæ of the last dorsal and two lumbar vertebræ, the middle portion of this section showing a crushed-in lamina. The patient began to recover sensation and motion within two weeks, and one month later had all the muscles restored excepting those supplying the left foot and ankle, which portion also remained without sensation subsequently. He was able to go about on crutches, but he demanded amputation of the left foot a year later on account of its dragging, so that he might use an artificial foot.

Operation in Cases of Fractured Spine.—Since 1875, when I had the opportunity of caring for my first case of broken neck under the guidance of Dr. Sabine, the attending surgeon at St. Luke's Hospital, I have watched the course of many victims of spinal fracture which were refused operative treatment; but ten years ago, under the stimulus of Thorburn's writings, I felt that these cases might have some little hope of relief held out to them; I now feel justified in saying that the operation presents little danger to the patient, and gives sufficient improvement to justify the time given to the operation. This improvement may not often be seen in the restored power of motion, but in minor evidences of the removal of the persistent meningeal irritation from pressure; relief of girdle pains, improved vasomotor conditions of paralyzed parts, and muscular twitchings. No surgeon would refuse operation for depressed fracture of the skull, leaving bone pressure to irritate the brain. I think it equally logical that the spinal cord should also be treated with the same care.

I have on several occasions in late operations upon spinal fracture found complete occlusion of the canal by adhesion of the meninges at the site of pressure, preventing the flow of cerebro-spinal fluid from above downward. I would repeat here, in brief, the method of operation for laminectomy devised by me, and which is the most simple and bloodless of all and gives perfect access to the cord.

Method: A straight incision, six inches long, is made a little to one side of the spinous processes, the knife passing between the muscle and the spines directly down to the laminæ; the muscles are then easily separated by blunt dissection from the laminæ on one side, and the tips of the spinous processes, with the interspinous ligament unbroken, are separated by cutting-pliers. These, with the opposite side muscle, are then easily dissected in the opposite direction, the muscles being very loosely attached to the laminæ, and the method comparatively bloodless. A rongeur is now used to gnaw away the base of the spines and as many laminæ as are required to expose the cord.

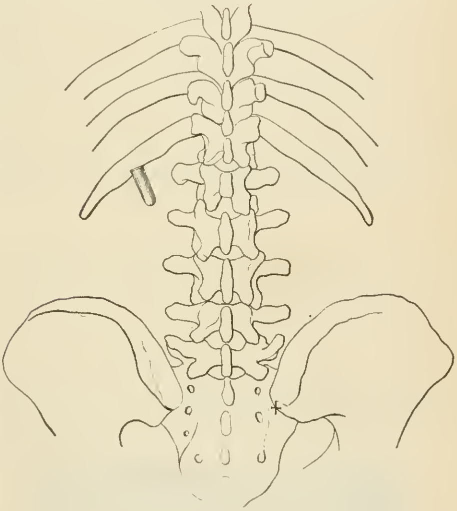

Fig. 2.

Summary of Observations.—The immediate signs and symptoms of fracture paraplegia give fairly accurate data for prognosis.

If loss of sensation and motion below the injured part is complete and instantaneous, and the patella reflex (knee jerk) is lost, the outlook for recovery is almost hopeless. Yet knee jerk, sensation, and motion may be absent, as in one case just reported (E. M——), and recovery takes place after operation.

Partial loss of sensation or motion gives hope that a large degree of recovery may be looked for, the cause in such cases being hemorrhage within the central canal or in the cord substance and meninges. Distribution and absorption of blood-clot take place usually within ten days or a fortnight, and returning sensation follows.

Return of motion in complete paraplegia cases does not always go on to perfect restoration. Wrist-drop of one hand, or dragging of one foot, may still remain two or three years after.

In cervical-fracture paraplegia the fifth vertebral body is most often injured, hence the phrenic nerve derived from the third and fourth branches of the cervical plexus gives the only supply to a respiratory muscle, to wit, the diaphragm.

The labored respiration by diaphragm only usually results in pulmonary œdema and hypostatic pneumonia a few days after the accident. This may be overcome by nitroglycerin internally and frequent change of posture.

Intestinal fermentation with temperature disturbance easily occurs in high paraplegias, and is speedily relieved by calomel.

Regeneration of a pulpified cord is impossible. Restored function is probably always due to absorption of blood, or of the secondary inflammatory deposits which prolong the pressure symptoms.

The persistence of bone pressure at the site of injury justifies operation as much as in depressed fracture of the skull, because through pressure an injured cord must be further degenerated.

Laminectomy should be done as promptly as possible. If the subject be favorable, it may be done by expert use of cocaine. It will be less painful if done before local meningitis sets in.

An *x*-ray view of the fracture can be readily taken in these cases by from ten to fifteen minutes' exposure, and greatly aids the surgeon.

AN EASY METHOD OF REDUCING DISLOCATIONS OF THE SHOULDER AND HIP.

By LEWIS A. STIMSON, M.D.,

SURGEON TO THE NEW YORK AND HUDSON STREET HOSPITALS; PROFESSOR OF SURGERY IN CORNELL UNIVERSITY.

DURING the last three months the following method of reducing anterior dislocations of the shoulder has been employed exclusively at the Hudson Street Hospital, and has proved so effectual and easy that I think it has earned the right to be more widely known.

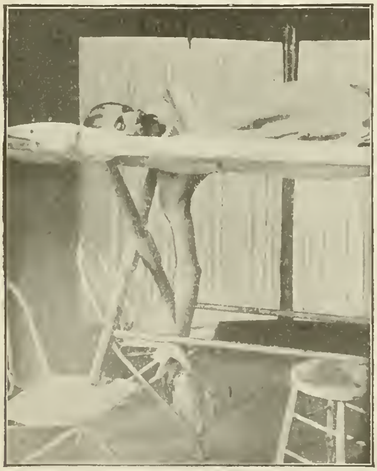

FIG. 1.—Reduction of Anterior Dislocation of the Shoulder.

I was led to devise it by the success that had followed the employment during a number of years of a similar method in reduction of dorsal dislocations of the hip. It has now been tried in about ten successive recent cases; it has failed in none, and has never required more than six minutes to effect reduction.

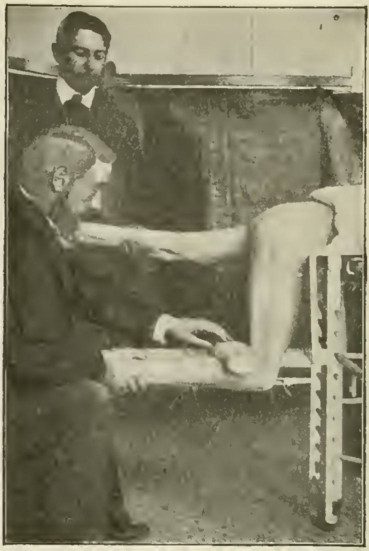

FIG. 2.—Reduction of Dorsal Dislocation of the hip. (Dislocation was not present in either of the patients photographed for these illustrations.)

The principle is that of steady moderate traction upon the arm in abduction, and the procedure is as follows:

A round hole about six inches in diameter is made in the middle of the canvas of a cot, about eighteen inches from one end. The patient is placed upon the cot with the injured arm hanging down through the hole, as shown in the illustration. The cot is raised upon blocks so that it will be at a sufficient height from the floor, and a ten-pound sand-bag is made fast to the wrist of the dependent arm. After a wait of a few minutes reduction is found to have taken place. None of the patients has complained that the procedure is painful. I recommend it as an effectual, easy, expeditious, and apparently safe method.

Theoretically it would be better to attach the weight to the arm close above the elbow, but in practice the wrist has proved to be the better place, for some of the patients would grasp the legs of the cot with the free hand, and thus interfere with the action of the weight. Possibly, lacking a cot, two tables might be used, placed end to end, the head resting on one, the body on the other, with the arm hanging down between. But the lack of snug support of the shoulder might induce a muscular effort, which would defeat or at least delay success.

The same method could be employed in dislocation of the elbow whenever the joint can be freely extended without the aid of anæsthesia, but under such circumstances traction by the hands alone is usually sufficient.

In dorsal dislocations of the hip the method is applied as follows: The patient is placed prone upon a table in such a way that his thighs extend beyond its end. The uninjured thigh is held horizontal by an assistant, to prevent tilting of the pelvis, and the injured one is allowed to hang vertically, while the surgeon, grasping the ankle, holds the leg horizontal (right-angle flexion at the knee) and gently moves it from side to side. If relaxation of the muscles is slow to appear, a sand-bag—five or ten pounds—is placed on the leg close behind the knee, or pressure is made there with the hand. This has succeeded in more than four-fifths of the cases in which I have employed it, and often without the aid of anæsthesia. In the two cases in which it failed, reduction was accomplished by traction in a line midway between right-angle flexion and full extension. I presume they were cases in which the bone had left the socket at a higher point than usual, probably dislocations "above the tendon," so called.

THE RELATIVE MERITS OF OPERATIONS FOR THE EXTRACTION OF VESICAL STONE IN THE MALE; WITH OBSERVATION ON THE SUPRAPUBIC AND LEFT LATERAL PERINEAL METHODS.[1]

By SCHUYLER COLFAX GRAVES, M.D.,

VISITING SURGEON TO THE U. B. A. HOSPITAL, GRAND RAPIDS, MICH.

Mr. President and Gentlemen: The index of merit associated with the performance of any surgical operation is the mortality rate. Where the figure is low, success is frequent; where the figure is high, failure comes far too often. Eyes beaming with gratitude are the handmaid of the former; and sighs and sobs the mournful accompaniment of the latter. That the joy of the world may increase, and the grief decrease, is the ever-present desire of the medical profession. We all know this, and are doing what we can to multiply the comforts of life and eliminate the woes by a constant endeavor to minimize mortality percentages. Trusting that the thoughts contained in this paper may be productive of good along this line, the same is respectfully presented.

Let us turn, first of all, to the mortality tables bearing upon this subject as prepared by J. William White for Dennis' "System of Surgery." These tables are arranged to cover the three operations done during three different epochs of life, viz., "(*a*) Infancy to puberty; (*b*) puberty to middle age; (*c*) middle age to old age," and are as follows:

a	1. Suprapubic,	13.1%.	*b*	Suprapubic,	11.3%.	*c*	Suprapubic,	18%.
	2. Perineal,	3.1		Perineal,	9.7		Perineal,	19
	3. Litholapaxy,	1.7		Litholapaxy,	4.5		Litholapaxy,	7

It will thus be noted that the Bigelow operation bears the lowest rate in each instance, and this fact is evidently due to the greater dangers at present connected with the cutting operations.

I now invite your attention, briefly, to a schematic exposition of the general merits and demerits of these three operations:

1. The Bigelow (litholapaxy): *A*, Advantages—(1) Avoidance of cutting; (2) abbreviated convalescence. *B*, Disadvantages—(1) Danger of damage to the bladder wall; (2) liability of laceration from incarcerated fragments; (3) Greater possibility of recurrence from failure to extract all particles; (4) poor drainage; (5) amount of time required; (6) inefficiency in case of very large calculi.

2. The suprapubic: *A*, Advantages—(1) Adaptability in case of large or impacted stones; (2) Ocular inspection and digital touch; (3) avoidance of hypertrophied prostate and tortuous prostatic urethra in the aged; (4) possibility of drainage. *B*, Disadvantages—(1) Danger of opening the abdominal cavity; (2) danger of sepsis from urinary infiltration; (3) Excessive detail in technique.

3. The perineal: *A*, Advantages—(1) Rapidity of accomplishment; (2) digital touch; (3) drainage. *B*, Disadvantages—(1) Hemorrhage: (*a*) artery of bulb; (*b*) internal pudic; (*c*) prostatic venous plexus. (2) Opening of pelvic connective-tissue planes, with sepsis from urinary infiltration; (3) section of ejaculatory duct; (4) rupture of entire urethra.

The operation of litholapaxy requires a very delicate and highly educated touch for its proper performance, and this means that many patients must suffer to enable the surgeon to develop that touch. It also often consumes considerably more time, even with the most skilled of operators, than prudence will permit, and furnishes real danger in the guise of laceration, infection, and the risk of recurrence. However, it must be admitted that when vesical calculus is very common, and under the old régime, this procedure, in the hands of the few, has given the best results; but in the hands of the many, and in localities where stone is not often seen, it is my sincere belief that the suprapubic or perineal methods, modified as will be observed later, will yield results in percentage rates fully as good as, and better than, those following litholapaxy in the same hands.

These modifications I shall now proceed to epitomize, and then discuss.

A, Improvements on the suprapubic method: (1) Horizontal incision; (2) Bristow's modification; (3) Harrington's modification; (4) Senn's modification; (5) writer's modification.

B, Improvement of the left lateral perineal method: Dilatation of the prostatic urethra, as well as the vesical neck, instead of section. Advantages: (1) Maintenance of prostatic and vesical integrity; (2) diminution in amount of traumatism; (3) avoidance of hemorrhage from prostatic plexus; (4) avoidance of damage to the ejaculatory duct; (5) avoidance of urinary infiltration; (6) avoidance of separation of bladder from urethra; (7) avoidance of much filthiness in surroundings; (8) more or less urinary control; (9) ease of drainage in cases requiring it; (10) rapid convalescence.

A (1) I cannot recall the reference; but some time ago my attention was drawn to an article by a Western surgeon advocating a transverse incision in cases requiring the high operation. This suggestion is a valuable one, and has been employed by the writer on several occasions since then with much satisfaction. The cases have not been lithotomies, for I have preferred the low operation in the stone patients who have come to me; but were cystotomies for (*a*) urinary distention from a hypertrophied prostate, and (*b*) urinary infiltration from a urethral tear made during the passage of a sound for stricture dilatation. The principle, however, is the same. The incision is made along the upper border of the pubis, and, in connection with other details, best exposes the space of Retzius (cavum Retzii), thus avoiding as much as possible the prevesical peritoneal fold. The tendons of the recti may be snipped or not as the case demands.

(2) Bristow, of Brooklyn, has developed an important modification of the high operation, and I would respectfully refer you to his original article.[1] His idea is to distend the bladder with air instead of water in the effort to render accessible the cavum Retzii. The doing away with the nuisance of stuffing the rectum with a water-bag, the diminished danger of vesical rupture from hydrostatic pressure, and the lightness, elasticity, and compressibility of air are advantageous points fully developed in his essay. Bristow originally inflated the bladder directly from his lungs,

---

[1] A paper read before the Calhoun County Medical Association, at Battle Creek, Mich., December 5, 1899.

[1] Bristow, A. T.: "The Use of Air to Dilate the Bladder in Suprapubic Cystotomy." Annals of Surgery, 1893, vol. xvii., p. 667.

although now he recommends a bicycle pump (a suggestion of F. Tilden Brown), used after the initial incision is made, in order to permit of inspection during the process; and he claims that by his method the peritoneum can be lifted from two to three inches above the symphysis without the use of a rectal bag, while the vesical injection of ten ounces of water will lift it only about one-half an inch under the same conditions. He also states that the injection of four ounces of water has caused vesical rupture.

Some criticism was offered as to the applicability of this plan in actual practice, Bristow having based his statements on cadaver experiments without reference to bladders altered by disease; but as high an authority as Professor Pilcher, of Brooklyn, came to the rescue by a practical substantiation of its claims, even in bladders softened by advanced disease and extensive ulceration, and since then Bristow himself has had abundant opportunity to prove the practical value of his suggestion. There can be no doubt, however, that in cases in which the bladder has undergone great inflammatory thickening and contraction, this procedure will, at least occasionally, be found inefficient if not actually dangerous. Such cases are not suitable for the suprapubic operation.

(3) In 1893 Harrington, of Boston, published an article[2] recommending intraperitoneal cystotomy in selected cases. This theme has been discussed, and several additional cases have been added to the record, by Richardson, also of Boston.[3] From a perusal of these papers it seems that this procedure is at times both justifiable and successful. Richardson's cases were lithotomies, and in neither of them was any prevesical space present or even obtainable, because of small or chronically contracted bladders. In one he managed to stitch the summit of the bladder to the abdominal wall, thus partially shutting off the general peritoneal cavity, opening the bladder through its anterior aspect; in the other this could not be done, and the bowels had to be protected solely by sterile gauze. In both cases the vesical cavities were packed with aseptic mull for several days, for purposes of drainage, and both patients recovered.

When the suprapubic route seems preferable in any case, and the cavum Retzii is found to be absent, the Harrington plan should be adopted. As a matter of fact, however, such a condition of affairs is not often observed, and the inherent dangers associated with the intra-abdominal section of a calculous bladder are sufficient to deter many operators from its performance.

(4) In an article published for Senn by the *Medical News*,[4] in 1893 (later than the Bristow essay), the Chicago man recommends a truly life-saving innovation in the performance of this operation, viz., division into two stages. He cuts to the bladder, then packs with iodoform gauze, and waits five days for the appearance of the "cobble-stone" granulations. In this way microbic infection and the absorption of ptomains from urine, often exceedingly offensive and poisonous, are almost entirely obviated.

(5) It occurred to the writer that he could contract Senn's five days into five minutes, by the use of the cautery, actual or chemical, or by some protective powder, as the stearate of zinc, and later this was successfully done in a cystotomy for urinary retention, the wound being thoroughly treated with the "solid stick" ($AgNO_3$). By this suggestion it may become possible to cut to and open the bladder at the same sitting, and thus save days of pain and delay and danger to the patient.

B. When about to do a lithotomy on a boy aged seven years (February 5, 1896), the knowledge that so great an operator as Sir William Ferguson had, in a similar case, completely severed the bladder from the urethra in his endeavor to dilate the parts with his finger, the accident naturally resulting in the boy's death, caused the writer to think of the advantage of instrumental over digital dilatation; and so, in this case, after severing the fibres of the compressor urethræ, an ordinary grooved director was slipped into the bladder, the staff was withdrawn, and the tips of a double uterine dilator were passed along the director's groove into the vesical cavity. The parts were then easily dilated so that the finger could readily be passed into the bladder, and at this juncture, with a Longyear forceps, the calculus, which was about the size of the terminal phalanx of the little finger, was withdrawn. The wound was packed and the bladder drained for eight hours, after which no urine came through the incision, micturition being accomplished normally. The convalescence was very rapid, as is the case generally with children.

If the parts can be dilated in the child, they ought to be dilatable in the adult, and it was not long before the opportunity to decide the matter came. A young adult, twenty-seven years old, had stone, of four months' standing, complicating a vesical tuberculosis. The bladder was very much inflamed, hemorrhages were frequent, and the urine was purulent and exceedingly foul. After some preliminary treatment he was placed on the table (March 5, 1896), and the deep tissues were exposed by the usual lateral incision. The membranous urethra alone was cut, the dilator being used as in the case of the boy, and the parts were readily stretched. Inasmuch, however, as the stone was a large one, and the patient was quite weak and also the subject of organic disease of the heart, I deemed it advisable to crush the calculus in order to save time. This young man acted as did the boy. His urinary control was almost perfect. He held his water, and, when the impulse came, voided it, the stream passing through both wound and penis, as in the case of perineal section external to the compressor urethræ. There was very little incontinence, and in spite of a delay of eight days from hemorrhage caused by the ravages of tuberculosis, as a result of which, upon the expulsion of clots, it was deemed necessary to institute siphon drainage, the wound closed the sixteenth day, the urine being voided thereafter through the normal passage until about the thirtieth day, when after considerable straining some urine forced its way through the site of the incision. From that time on a tuberculous fistula persisted.

The question naturally arises: Was the outcome in these two cases exceptional or the result of prostatic and vesical integrity, purposely maintained? I think the latter, particularly in the case of the adult.

Although the idea of dilatation was original with the writer, he has since learned, by reference to the history of lithotomy, that it has been practised by mediæval and later operators, although not in the same way. Two methods are described:

Forcible dilatation, the so-called Marian operation, named from Marianus Sanctus, a pupil of the celebrated De Romanis, an Italian operator of the sixteenth century. This plan consisted in forcibly dilating the parts until they ruptured, the idea being that cutting was more dangerous than tearing. The results, however, must have been equally disastrous.

2. Gradual dilatation, the method of James Arnott, an Englishman of the earlier portion of the present century. He recommended gradual dilatation, ex-

[4] "Suprapubic Cystotomy in Two Stages." Medical News, July 1, 1893.

tending over hours or days, by hydrostatic force applied through the proper placing of a dilatable bag at the neck of the bladder. The method has never been much used.

Turning to the dicta of modern operators let me quote: The section of both prostate and bladder is to-day recommended by White (Dennis' "System"); Thomas Bryant ("American Text-Book of Surgery"), Wyeth, Moullin, Jacobson, and Treves. Roberts cuts the prostate alone. Joseph Bryant cuts the prostate and dilates the vesical neck, and so do Morrow and Keyes, the latter two also recommending section of bladder neck in the case of children. All recommend section of the prostate, and almost all section of the vesical neck as well.

The prostatic urethra and neck of the bladder can be readily dilated. Leidy[1] states, in reference to the prostatic urethra, that "it is the widest and most dilatable portion of the canal," and Roberts[2] speaks of "dilatation of the prostatic urethra and vesical exploration."

No modern author, as far as my observation goes, recommends the innovation which the writer offers, and no author, of any age, recommends the same procedure.

A word in possible explanation of the evidence of more or less urinary control following the modified operation. In doing the operation on the old plan it will be noticed that there are occasionally two separate gushes of urine, one when the fibres of the compressor urethræ are severed, and the other upon the division of the prostate and vesical neck.

Henry Morris,[3] in discussing the prostate, says: "The organ itself is composed of muscular and glandular tissue. The muscular element represents about three-fourths of the entire mass, and consists principally of unstriped fibres, continuous above with the vesical sphincter, and forming in the upper third of the organ a ring of great firmness and strength, lying above the urethral orifices of the ejaculatory ducts, and discharging in all probability the function of intercepting the backward flow of semen and prostatic fluid into the bladder during sexual congress."

Again, in reference to the presence and nature of the vesical sphincter, I quote from Leidy:[4] "At the neck of the bladder the internal (muscular) stratum is thicker, and thence extends upon the urethra, where it forms the circular vesical sphincter."

Associated with these unstriped fibres is more or less elastic tissue, adding strength and solidity to the compound. The phenomenon of double gush during the lateral lithotomy incision is thus explicable. Now, if the prostatic sphincter can prevent the backward flow of semen, it can at least assist materially in preventing the outward flow of urine, and thus it can be seen that, after the operation described above, the muscle, itself unimpaired, together with a tonic sphincter vesicæ, can account for post-operative urinary control.

Gentlemen, I cannot consider it bad surgery, even with the evidence of litholapaxy statistics, to recommend for the aged, for those who have enlarged, inflamed, and lobulated prostates, the modified sectio alta, and for the middle-aged and the young the modified sectio lateralis.

Bleeding of the Gums after Extraction of Teeth.—In five severe cases J. Munk (*Aerztlicher Central-Anzeiger*, 1899, No. 27) has seen almost immediate cessation of the hemorrhage follow the placing of a stypticin tablet upon the previously cleansed gum.

THE APPLICATION OF THE ELECTROSTATIC WAVE CURRENT.

By WILLIAM BENHAM SNOW, M.D.,

INSTRUCTOR IN ELECTROTHERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Since the introduction of this new contribution to electrotherapeutics by Dr. W. J. Morton, those familiar with it have had reason to congratulate themselves on the possession of a more potent agent than any of the older electric currents. The writer's familiarity with the current, having used it now for more than a year in private practice and in the electrotherapeutic clinic at the New York Post-Graduate Medical School and Hospital, furnishes material for the following observations.

During the summer of 1898, a patient under two months' treatment for a condition of general decline due to advanced age, receiving treatment of one-half hour's duration three times each week, made such marked improvement that it became evident that this current was an agent of no mean value. In this case a spinal electrode of sheet lead one and one-half inches in width, and ten or twelve inches long, was applied over the spinal column in close contact with the skin. The patient became stronger, and all his functions resumed their normal tone and activity, while he was receiving no other treatment, and this during the depressing humidity of that summer in town. Realizing that one case would not establish a precedent, but confident that to it much was due, I began to use the new current in all cases of malnutrition, neurasthenia, insomnia, and migraine, and in every instance was reassured and gratified with the result. In these cases I employed a block-tin electrode about one inch in width and sixteen to twenty inches in length, applied next to the skin over the vertebral column.

In patients whose secretions were inactive, marked improvement took place in every case. A patient who would barely perspire under the plate at the first sitting would perspire sensibly over the whole surface after the third or fourth application, and the feeling of exhilaration that followed each treatment for a few hours would become longer, until a sense of well-being became constant, with improvement in appetite and all other functions. This will be true in cases in which no serious organic disease exists, and even these will receive proportionate benefit. When such cases are treated and muscular contractions do not interfere (as they may when the patients are spare, with muscles well developed) a spark gap at least four inches in length should be allowed to discharge between the balls of the prime conductors, after the first tingling sensation disappears, which will be when the surface becomes moist between the surface of the body and the plate electrode.

These treatments should not be for less than twenty minutes, and daily for the first week or more, as the case may require.

In cases of headache or neurasthenia, the point electrode, having a good ground connection, should be placed over the head or on a level with the knees in front, and in either case at a distance just far enough to allow the spark gap to discharge uninterruptedly.

Patients of a congestive type and full habit are usually benefited by placing the point in front of the knees, causing the main drift of the current to flow in that direction, while weak or anæmic patients feel greater relief when it is placed over the head.

The anodyne effects of the current were not realized until the writer, after failing to give relief in an acute case of tic douloureux with the friction spark and short sparks, when treated for upward of half an hour, succeeded on the following day, after fifteen minutes' application of the "wave current," in completely relieving the pain for fifteen hours, when it returned with much less severity. No other anodyne had given so much relief with one administration for so long a time before, and when followed up for five days it effected a complete cure. Other cases of severe neuritis, as sciatica and brachial neuritis, have been completely relieved and cured in my practice without recourse to other measures, which establishes beyond question the claim. Attacks of neuralgia, when not due to pressure or necrosis, are without exception promptly relieved by the same method.

[2] "Modern Surgery," p. 690.
[3] "Human Anatomy," p. 1037.
[4] "Human Anatomy," second edition, p. 631.

The next surprise was received when the writer sought to relieve a timid patient who came to his office suffering from a swollen and painful knee joint (rheumatoid arthritis), without recourse to sparks. The joint was put up in a bandage of block tin, and the current, with a four-inch spark gap discharging, was continued for twenty minutes. The relief was so complete that the patient left without limping, after having suffered and grown worse for seven weeks. In a few weeks this patient, the first case of joint disease treated by the "wave current," was completely relieved, and has remained cured for one year. Since then many similar cases, as well as sprained joints, have been greatly benefited or cured by the same treatment.

Dr. Gibson, of Birmingham, Ala., reported at the meeting of the National Association of Electrotherapeutists, held in Washington in September last, a case of acute rheumatism in which a complete cure was caused by one treatment.

The treatment of paralyses by this wave current is far more satisfactory in our hands than by any other current. I find, however, in some forms that combining it with sparks gives best results.

This current is administered without the least unpleasant sensation as soon as the skin once becomes moist beneath the metal electrode, unless it is given strong enough to cause muscular contractions. It may be administered in any of the cavities or canals of the body without discomfort if metal electrodes are used without insulation. The results as far as known are most satisfactory, excelling and fully succeeding the sinusoidal and faradic currents whenever this treatment has been adopted. New fields for the use of this current will suggest themselves as time goes on, and the greatest of electric currents for therapeutic use will find new friends who must concur in the above statements, which are not at all extravagant. Before condemning it, every detail of the technique must be understood and practised, and those who ridicule the electrotherapeutist because the subject is too technical for their investigation will realize, after all, that he has at least one agent potent to relieve human suffering.

That there may be no misunderstanding, by those who have machines, in properly managing the current, I will briefly add the essential features:

1. Ground one pole of the machine to a gas or water pipe. A good ground is imperative, and the matter of polarity, so far as known, is immaterial.

2. Always treat the patient on the insulated platform.

3. Always employ metal electrodes (lead or block tin are best because pliable), and see that no material is between the electrode and the patient's skin.

4. Connect the patient by one rheophore, or more if several joints or parts are being treated at one time, to the side of the machine not grounded.

5. Close or nearly close the prime conductors, and start the machine.

6. Gradually separate the prime conductors until there is commencing discomfort from muscular contraction, or a burning sensation, which will disappear as soon as the skin becomes moist, or pain if applied over a neuritis. After short intervals the spark gap may be increased from time to time to get the best results.

7. In treating a neuritis do not make the electrode too large, or the current will be too much diffused to produce the best result.

8. Allow no object that would draw off the current to come near the platform, and be careful that no one touches the patient, for obvious reasons.

There are very many lesser details, but the above I believe sufficient for practical application; but every one is essential.

Clinical Department.

ONE RESULT OF ATTEMPTED ABORTION IN THE EARLY WEEKS OF GESTATION.

Dr. L. S. Alexander, of St. Augustine, Fla., writes that in many cases of tubal pregnancy he has, on close questioning, obtained a history of attempted abortion by drugs. The attempt is made almost immediately upon the non-appearance of the desired menstrual flow, conception being feared, to establish the catamenia by the use of oxytocic drugs. The action of this substance in contracting the circular muscular fibres prevents the descent of the fructified ovum, and tubal pregnancy, followed by rupture, results. In the South a favorite combination for this purpose is a mixture of cotton root and ergot.

PEANUT IN THE AIR PASSAGES.

By R. C. SHULTZ, M.D.,

LOS ANGELES, CAL.

This case is of interest only as adding to the statistics of results of foreign bodies in the air passages without operative interference. A girl, fourteen years of age, while buggy-riding with another miss, got some peanuts, which she was eating, into the air passages, and coughed most violently. She continued having attacks of coughing, and a whistling sound was audible part of the time to people in the room. A few days later a general practitioner made examination and expressed the opinion that the foreign body was in the right bronchus. An intended railway journey of some days was postponed, but was carried out without untoward incident between September 27th and October 6th. On the latter date I made a casual examination of the chest and distinctly heard a prolonged whistling, moaning, uncanny sound, only on expiration, all over the chest, but loudest a little above the right nipple and at the same level behind. At some subsequent examinations the sound was audible on inspiration, or on both inspiration and expiration, and with varying intensity, being occasionally heard, after coughing, at a distance from the patient.

On October 8th, after exposure, she had a severe nasal catarrh and enlargement of the tonsils. This had about subsided when, on October 16th, she had a most severe coughing spell, and coughed up profusely (which she had not done before); she felt some peculiar body reach the upper air-passages, which after a moment was expelled forcibly on the floor. The mother and the patient said the body was of the size and shape of a complete peanut kernel, hardest within, and which crumbled when picked with a pin. They felt sure it was the offending peanut. The patient experienced immediate relief and soon quite ceased to cough.

The same evening I was able to hear only a few coarse râles over the lower right lung; the whistling sound had disappeared; the breathing was deep and free over the entire chest. The patient's risibilities are very excitable, and I have cautioned her, as I think all ought to be, against uncontrollable laughter during eating.

VACCINELLA.

By E. V. MOCK, M.D.,
CAMBRIDGE, ILL.

READING the account in the MEDICAL RECORD of the patient with tertiary syphilis who after vaccination developed "vaccinella" brings to mind a case of which I kept a record while house surgeon of the workhouse hospital, Blackwell's Island. The patient was a woman, aged thirty-five years, admitted to the medical ward of the prison hospital with a severe attack of lobar pneumonia. She had fallen asleep in the street, drunk, during a cold rain, and was arrested and sent to the workhouse. Besides the pneumonia she had an extensive ulcer above the knee, which I diagnosed as specific after obtaining a history of syphilis of five years' standing. By the tenth day her temperature was running at 99° F., and she seemed in a fair way to recover, when she suddenly grew worse and the temperature rose to 104° F. Within a few hours an eruption appeared on her breast, spreading to her arms, abdomen, and legs. The eruption progressed from macular to papular, to pustular, and resembled so closely a smallpox eruption that I asked an attending surgeon to see the case. He advised isolation, and the sending for a dermatologist from the health board, which I did. After the pustular stage was well developed, the health board dismissed the case as one of tertiary syphilis. During the last stage pulmonary gangrene developed, and the patient died on the twentieth day after admission to the ward. The similarity of the two cases was such that I thought a comparison might be of interest.

SURGICAL ODDS AND ENDS.

By WILLIAM ANDERSON PAYNE, M.D.,
PATHOLOGICAL INTERNE, KINGS COUNTY HOSPITAL, BROOKLYN, N. Y.

AT St. Mary's Hospital, Hoboken, N. J., I met with the following cases that I hope will be of interest to the profession, not so much on account of their practical bearing, as for the lesson they teach one to be prepared at all times for all things. The conditions here presented are rare, if I may be allowed to judge from the statistics at hand.

CASE I.—Fracture of the mandible at both angles. This case I saw in consultation with Dr. Stack. The patient, eighteen years of age, was hit by a thrown brick on the side of the lower jaw, while walking through an ill-lit park. Nothing presented to make him think of fracture, and he thought the jaw merely out of place, until on examination the next day we assured him of the true condition. He could make himself well understood, and in articulating moved the symphysis considerably. He could eat food that required no chewing, and complained of nothing save slight pain, greatly increased on moving or manipulating the maimed member, and deformity. On inspection there was much swelling at both angles of the jaw, not unlike a double parotitis, and had I not observed the deviation of the chin to the left, I would surely have thought of that condition. The mouth was open and he could not close it. The manual examination showed free motion of the symphysis downward and upward, as well as from side to side, yet in this latter attempt I failed to bring the chin to the middle line. Grasping the molar teeth with two fingers, I found that I could move the ramus of one side with my other hand, and this procedure and result I demonstrated on the other side as well. The mucous membrane was untorn. So easily did I obtain the false points of motion and crepitus that from these signs alone I was warranted in making the diagnosis. The deformity and position left no room for doubt. With my thumbs in the mouth and fingers grasping the lower border of the bone, I reduced the fracture, and maintained the jaw in its proper place by a plaster splint, moulded snugly, and so broad as to embrace the angles thoroughly. The line of fracture on both sides was quite the same, extending from behind the last molar teeth to the angles.

A fracture at this point is not common, and when it occurs on both sides and with such manifest symmetry it becomes rare indeed. The mild type of symptoms should also be noted, and it would really appear as though a double fracture of this nature would be preferable to the usual single and compound fractures of the symphysis. These fractures, besides being simple, were unaccompanied by injury to the contents of the inferior dental canal. The attachment of the masseter muscle to the fragments of both sides must be given credit for the mildness of the subjective and objective symptoms, for it bound the pieces together and constituted a natural splint and at the same time lent its action to either fragment. After four weeks the patient was quite well and without deformity.

CASE II.—Rupture of the internal lateral ligament of the knee, with gunstock deformity of the leg. This patient was a strong, robust man, aged thirty-one years. He fell from a scaffold twelve feet high, and landing on his outstretched feet was thrown forcibly to his right. He was unable to arise, and was brought to the hospital in the ambulance. On examination I found his leg occupying an angle of 135° with his thigh. With little force this angle could be made more acute, but all efforts to reduce the deformity failed. The inner hamstrings were quite taut, but none of them was ruptured. The inner portion of the capsular ligament had been torn across, and the ruptured ends of the internal lateral ligament could be felt in their retracted positions. In this rent I could thrust my finger tips between the intact head of the tibia and the inner condyle of the femur, and in this intervening space I could feel what I believed to be the dislocated internal semilunar fibro-cartilage. To its detached presence between these articular surfaces I attributed my failure to bend the leg inward to its normal position. It greatly hampered, furthermore, the movements of flexion and extension, and only through a very small arc and with great difficulty could I accomplish this movement.

By manipulation with the fingers of my right hand in the situation described, and by vigorously moving the malplaced leg with my right hand, I was suddenly conscious of a click, and the leg once more occupied its normal position. This click was produced by the slipping of the cartilage into its proper site. The inflammatory reaction was great, but after several days spent in combating it the whole limb was encased in plaster. At the end of six weeks this was removed, but so weak was the joint that a reapplication of plaster was deemed necessary. It, however, bade fair finally to regain its strength. At this point I lost sight of the case.

CASE III.—Inward dislocation of the foot, without fracture. This man, aged thirty-three years, stepped on the end of a plank; the other end went up, and he was thrown forcibly on his left side. He managed to get to a car and from the car walked unaided into the hospital. His right foot was dislocated inward. If it had been outward instead, one would, after inspection, have diagnosed it as a Pott's fracture with the accompanying deformity. The sole of the foot, however, was parallel to the floor. The foot was pushed inward, and the internal malleolus rested on the middle of the trochlear surface of the astragalus. This malleolus being intact, I was curious (and am yet) to know how the inner articular surface of the astragalus passed under it and to its inner side. Surely it could not have passed directly inward, for the projecting malleolus and the capsular ligament offered a formidable barrier, to say nothing of the adjacent prohibitory structures. To go around the malleolus would have been easier, and I am forced to conclude that this is what happened. Considering the articular surface of the astragalus as a segment of a wedge with its base forward, we must regard the route pursued by this in freeing itself of the malleoli on either side as a forward one. When it had passed sufficiently far anteriorly the inner malleolus slipped outward on its posterior surface, and from this situation the malleolus passed forward, by the flexing of the foot in walking. So we find the tip of this process resting firmly against the centre of the trochlear surface, probably indenting it, and maintained in this position by the strong upward pull of the adjacent ligaments and tendons. The external lateral ligament was ruptured; the internal one was not and could be felt as a taut band running from the malleolus almost horizontally inward to the displaced astragalus. On the outer side the malleolus had nearly penetrated the skin and was felt beneath it as a sharp projection. At one point I could pass my finger between the outer surface of the astragalus and the inner surface of the malleolus. With the patient under chloroform I succeeded by repeated efforts in forcibly replacing the foot. The patient remained five weeks in the hospital, and was left without deformity and with a leg of normal usefulness.

Case IV.—Fracture of the fourth metatarsal bone. How a force of any kind could act on one of the inner metatarsal bones alone is rather remarkable, unless it be from some pointed object. This case, however, presents further interest, in that the man with foot strongly extended had the anterior part of the sole and toes come in contact with the pavement. I shall not attempt to disclose the selective action of this particular pavement. There was swelling over the outer part of the foot. A tap on each of the toes elicited pain only when the fourth toe was struck. I could get fremitus and a false point of motion, and these combined with the signs above brought me to the diagnosis as recorded.

Case V.—Incised wound of the ischio-rectal fossa produced by breaking of a chamber vessel. These trips to Chinatown are not infrequent, and I do not mention it on account of its oddity, but rather to show the beautiful effects of saline infusions in the treatment of hemorrhage.

This heavy old woman produced by her great weight breaking of the night-glass beneath her, and incurred thereby a wound four inches long, extending deeply into the ischio-rectal space. When she reached the hospital it was quite evident that a severe hemorrhage had occurred. All the symptoms of hemorrhage were present, but the absence of the radial pulse alone sufficed to indicate that our patient was on the verge of death.

Besides the usual remedies we started the flow of saline solution into the buttocks and beneath the breast. Gradually the pulse increased in strength, and the patient before long was placed on a fair basis of life. By far the greater part of this improvement was directly traceable to the salt solution. I could feel the pulse come up as the fluid filled the vessels. Unfortunately the patient died of hypostatic pneumonia two weeks later. The danger of such accidents impresses upon one the fact that beneath the bed there often lurks the enemy of womankind.

HYPODERMOCLYSIS IN TYPHOID FEVER.

By O. O. BURGESS, M.D.,
SAN FRANCISCO, CAL.

In typhoid fever several important factors are regularly or occasionally at work to reduce the quantity of circulatory fluids in the body. Among these may be mentioned the increased consumption of fluids incidental to febrile movement; the lessened absorptive activity of the stomach and intestines, hemorrhage, colliquative diarrhœa and sweating, etc.

In view of the fact that solutions sufficiently salt to provoke increased endosmosis cannot, consistently, be introduced into the stomach and by way of the stomach into the intestines, why should it not be good practice to use the decinormal salt solution, upon occasion requiring it, by way of high rectal injection if practicable, or by hypodermoclysis, or in emergency by the intravenous method? In addition to the usual advantages of hypodermoclysis, we should thus secure the introduction into the blood-vessels of a pure liquid, uncontaminated by the bacilli and ptomain products which liquids by way of the stomach and intestines are pretty sure to pick up, and the probability of decreased exosmosis should not be lost sight of.

Indications for the use of the decinormal salt solution should not be limited to hemorrhagic cases, but the method should be resorted to in all cases in which the usual methods of treatment fail to accomplish the desired result. It seems highly improbable that any harm could come of it.

THE AUDITORY CANAL AS AN INCUBATOR.

By A. J. HOLMQUIST, M.D.,
COMO, COLO.

R. B——, male, aged seventeen years, presented himself for treatment late in the afternoon of August 14th, with the following history: While out on a fishing trip, a fly, supposedly a blue-bottle, had entered the left auditory canal. From the irritation produced and the consequent buzzing he supposed the offending object still present. A speculum was introduced, but examination revealed only a mass of cerumen impacted against the drum. As this was easily accountable for the buzzing I naturally discredited the patient's statement concerning the fly in his ear, especially as examination revealed no trace of it. Hence my first treatment was directed toward clearing the canal of its accumulated cerumen. A softening mixture of glycerin and water with sodium carbonate was prescribed for use at home, and a pipetteful of pure hydrogen peroxide was instilled into the canal. This was followed by syringing, which resulted in bringing away only a few small flakes of wax. The patient here stated that his mother had introduced some warm lard into his ear to allay the irritation. This having united with the cerumen probably accounted for the syringing being so ineffectual. On the patient's return the next afternoon he complained of intolerable buzzing and acute pain. A few drops of blood also had oozed from the canal. Examination, as before, was negative except revealing the mass impacted against the drum. Hydrogen peroxide was again employed in full strength, followed by syringing, which failed to dislodge the wax. Two hours later the patient returned with a living maggot, which had wriggled out of his ear. A mixture of alcohol and turpentine, equal parts, was prepared, and between fifteen and twenty drops introduced into the canal, the patient's head being held so that the full effect of the medicament could be exerted against the drum. He complained of excruciating pain and increased buzzing. As soon as the latter ceased the head was inverted and irrigation with warm water from a fountain syringe was employed. This resulted in the expulsion of a dirty mass of detritus containing two dead maggots. A quarter grain of morphine sulphate dissolved in warm vaseline followed the irrigation, to allay the pain caused by the turpentine, and no further trouble was reported. A week or two afterward the patient, on being questioned, remembered that before applying for treatment he had removed from his ear between twenty and thirty white, elongated objects which resembled the larvæ of an insect. This would account for the small number (three) of maggots being found, as the detritus from the last irrigation revealed no larvæ. What seems a remarkable feature is the short time required for the incubation of the larvæ, as only twenty hours elapsed from the time the fly entered the ear until bleeding from the canal occurred. However, the medium of the warm lard and the normal body temperature must have proved favoring factors to rapid incubation.

FLOATING KIDNEY MISTAKEN FOR AN APPENDICITIS AND OVARIAN TUMOR—OPERATION AND RECOVERY.

By H. T. MILLER, M.D.,

SURGEON TO MITCHELL-THOMAS HOSPITAL, SPRINGFIELD, OHIO.

In a recent issue of the Medical Record, there was reported a case of "nephrorrhaphy and stripping of the appendix through lumbar incision for floating kidney and painful appendix." Though the case I am about to relate is not a parallel one, yet it suggests the possibility of mistaking a right floating kidney for an appendicitis, or, in a woman, for an ovarian tumor.

Mrs. R——, aged forty-four years, occupation domestic, entered the hospital on March 29, 1899, suffering from pain in the right iliac fossa, about one inch below McBurney's point. This pain had commenced about one year previous to the above date, and had continued up to the time of operation. During this period an enlargement made its appearance in the right iliac region. A few days previous to the operation an examination could not determine anything distinctly characteristic in the outlines of this tumor to prompt an absolutely positive diagnosis, nor did the subjective examination determine anything further than that the patient was incapacitated for about a year by almost constant suffering from pain in the right iliac fossa. At infrequent intervals there was a slight rise of temperature.

The outlines of this tumor were not at all distinct, and because of its location it could easily be mistaken for either an appendicitis or an ovarian tumor; then, moreover, the subjective examination could not determine whether the enlargement had appeared gradually or suddenly, whether it was preceded or followed by pain, or whether the fever was short or long in duration; in fact, the history of the case was *nil*. However, the opinion seemed to favor the possibility of the tumor being ovarian, so it was not a little of a surprise when, upon exploration by median incision, a right floating kidney was discovered.

In order to complete the history of the case, I would add that the median incision was at once closed, and a lumbar incision was made, commencing at the twelfth rib to the crest of the ilium. In order to get hold of the kidney and bring it to the margin of the incision, a pair of vulsellum forceps was used, and the organ was secured to the posterior abdominal wall by three large-sized interrupted catgut sutures, no drainage being used. The patient left the hospital on the sixth of May following, cured.

A recent examination showed the kidney still securely anchored.

CONGENITAL HERNIA OF THE UMBILICAL CORD.

By GEORGE KESSEL, M.D.,

CRESCO, IA.

In the Medical Record for November 4, 1899, is an article on "Congenital Hernia of the Umbilical Cord," with a history of two cases. I want to add the history of a case.

On August 2, 1899, I delivered a healthy woman in her first confinement of a healthy girl baby. The labor was normal. But I was astonished when I took my first look at the child and saw the large hernia of the cord. The coils of intestine and the liver could be seen clearly through the transparent membranes of the cord. Apparently all the abdominal viscera were in the tumor, which was as large as the child's head. These contents could be easily reduced. Being afraid to leave the tumor over night as it was, I immediately performed the operation of stitching the freshened edges of the incomplete umbilical ring together with silk. But the child died during the night. Death seemed to me to be due to the pressure of the abdominal contents within the abdomen, for every time I reduced the contents the pulse weakened and failed, and upon relaxing the pressure it grew strong again. If I ever see another case of the kind I shall wait a day or two before I operate.

A CASE OF TETANUS IN WHICH THE MOUTH WAS THE PROBABLE SOURCE OF INFECTION.

By E. K. LOVELAND, Ph.G., M.D.,

WATERTOWN, CONN.

During the night of September 19th, I received a hurried call to see a child. The messenger said the little patient had just had a severe convulsion, and he wished me to get there as soon as possible. On arriving at the house about an hour later, I found a healthy-looking, well-nourished, plump, and exceptionally bright-appearing, twenty-months-old girl sitting in the lap of an anxious mother. On inquiring into the history of the case, I found that the child had been unusually healthy during her entire life up to the present sickness, which commenced two days before, when it was noticed that she awoke from her afternoon nap with a sudden start, crying. Her parents thought nothing in particular of this at the time, as the child had played exceptionally hard before her nap and continued to do so during the rest of the day. That night the child awoke once or twice with a sudden start, crying for a second or two as if in severe pain, but dropped off to sleep again very soon, and the parents attributed it to her having become over-tired the day before. The following day she seemed well and had a good appetite, but during the night that followed, she had a repetition of the symptoms of the night before, except that the spasms of crying and sudden awakening seemed to be more severe; but in the morning she seemed quite bright again and also through the day, eating well; but they noticed that she acted as if her throat were a little sore. The next night (September 19th), the little one awoke suddenly out of a sound sleep, and crying out as before went into a convulsion, upon which they sent for me. At this time when I reached there, as I have already stated, she was very bright, sitting in her mother's lap, but had a temperature of 100° F. with a tense, rapid pulse. She dropped to sleep repeatedly while in her mother's lap, as often as once in five minutes, and each time awoke with a terrible jump and a contraction of the muscles of the back of the neck and throat, which lasted but a few seconds and then passed off, and the child again dropped off to sleep. On trying to open her mouth to examine her throat, I found that I could not separate her jaws, which were tightly closed, and although she was a bashful child, and generally cried when strangers were present, yet she did not do so now. The parents said that they had also tried once or twice that day to see her throat, but could not get her mouth open. I left her some bromide, also some aconite to reduce the fever and tension of the pulse.

I called the following morning and found that she had had no more convulsions nor much sleep since the night before, owing to the fact that she could sleep but a few minutes before she would be awakened by a sudden contraction of the muscles, followed by a peculiar cry, probably due to pain; but she would not weep, nor did she from now on, during her entire sickness. The muscular contraction and cry during the past twelve hours had not seemed to be quite so severe, probably due to the bromides; her temperature was now 99° F. and the pulse was not quite so full and snappy as it had been the night before. When evening came I found her with a pulse more rapid and fuller, with a temperature of 101½° F., and she had had two spasms during the day; the jaws were tightly locked, and in trying to open them they were strongly forced together and closed so firmly upon the spoon handle that it was really with difficulty that I could remove it, and on doing so I found the print of her teeth upon the spoon; the patient immediately went into a spasm, probably due to the irritation, in which the opisthotonos was very marked and there was a marked sardonic grin. I then felt confident that I had a case of tetanus to deal with, and, although the parents had told me two days before that there were no scratches, cuts, or sores of any kind on the child, yet I examined her carefully myself to see if I could find any kind of flesh wound. On the calf of her leg I found where there had been a slight scratch, said to have been three weeks old; it was about a half inch long and the scab had already dropped off; there was no inflammatory action present, it being entirely healed and well. There was only one other mark anywhere on the child's skin, and that a very small scar, over the left eye, which was due to a dog having bitten her five months before, but there was no inflammation here nor did any develop during her sickness, and the dog is still living and well. There seemed to be considerable trouble somewhere in the throat, as there was a large amount of ropy mucus, mixed with pus and blood, with a powerful odor, which was constantly discharged from both nose and mouth, and her neck was swollen over the tonsils; but as yet I had been unable to get her mouth open enough to examine her throat. I left instructions with the nurse to increase the dose of bromides and give three grains of chloral each three hours. The next morning (the 21st) she had slept more, and yet had had two or three spasms during the night. She was still taking some nourishment from her nursing bottle, she herself folding the rubber nipple and crowding the same between her teeth at such times as she was able to get her teeth apart, the opening probably amounting, at the most, to something less than a quarter of an inch. I wished for counsel, and Dr. E. C. French, of Watertown, met me with the patient that afternoon. We considered the antitoxin treatment, but it was not thought favorably of by the family and we did not press it. We now felt that she was getting neither the nourishment nor the stimulant by the mouth that she needed, so we commenced giving her pre-digested food with stimulants by enema; also the chloral and bromides with a very little morphine were given by the rectum, and pushed almost to the extreme of tolerance during the night, as the spasms and opisthotonos had been repeated at intervals of a very few minutes all day, and the risus sardonicus was now almost constant. The child had worked at her nose almost constantly during her sickness, crowding her little fingers into her nostrils as far as she could. I examined her nostrils as far back as possible, using my head mirror. As far back as I could see there was considerable inflammation, and at this time there was an increase of the flow from the nostrils of a sero-sanguineous pus, which had an extremely sticky consistency, and this continued to increase up to the child's death four days later.

The next day the temperature went down to normal, where it remained. The pulse was short and snappy, but was readily softened by the use of veratrum viride. The following day the jaws relaxed fully three-quarters of an inch, and the spasms were not so intense (probably due to the use of anodynes), and, on examining the posterior nasal pharynx with a head mirror, I found quite a large sore on the back of the mouth surrounded by a boggy, honeycomb tissue which involved uvula, tonsils, base of the tongue, and particularly the palate, and this was, I believe, the original site of the infection. I then asked if the child had at any time been putting things into her mouth while at play from which she could have received any injury. The parents recalled that, two or three days before she was taken sick, she was playing in the attic with a kit of old cobbler's tools, belonging to her father, and they thought that she put some of the tools in her mouth, and said that she might have got scratched in that way, although they did not remember hearing her complain. My belief is that she, while playing with the rusty nails, awls, etc., to which more or less earth was adherent, put them in her mouth, and from these received a slight scratch on her palate, and this was the source of tetanus infection.

AN UNPRECEDENTED CASE OF PROLONGED ANÆSTHESIA WITH NITROUS OXIDE AND OXYGEN.

By S. ORMOND GOLDAN, M.D.,

NEW YORK.

SELDOM if ever can the efficacy of any anæsthetic be more severely tested than in the following case:

Mrs. J——, aged seventy-six years; general condition fair; type of patient anæmic though stout; previous narcosis, none; respiratory system normal, though respiration was slightly increased in frequency, being 24; circulatory system normal; slight arteritis considering the age of the patient, arterial tension slightly increased; pulse, 84; urine analysis negative. The anæsthetic used was nitrous oxide and oxygen throughout. The operation was for extirpation of both breasts with axillary contents, the narcosis lasting two hours and forty minutes.

Dr. Hewitt's apparatus was used with Barth's arrangement of cylinders. the precaution having been taken to turn the stopcock at right angles to the face piece, which I have found by experience, in using this apparatus with the patient in the recumbent position, insures more perfect working of the valves, which is of the greatest importance when using the mixed gases.

The percentage of oxygen during the first half of the anæsthesia varied according to this apparatus between six and eight per cent., during which the patient's pulse averaged about 70; respiration about 20; the pupils were normal, or moderately dilated. Cyanosis was entirely eliminated; in fact, the patient's color was better than before the administration was commenced. There was some slight venous oozing during this part of the operation. During the second part of the operation I found the patient stood ten per cent. of oxygen, and only at twelve per cent. or more did she evince signs of returning consciousness. There was no venous oozing during this part of the operation. I found no stimulation necessary before, during, or after anæsthesia, nor did any untoward symptoms develop. Consciousness was regained immediately upon removal of the inhaler, and no excitement developed, which is not infrequent after the use of nitrous oxide and oxygen. Following the removal of the inhaler the patient objected in vigorous tones against the application of dressings and tight bandages, which shows the transitory effect of this anæsthetic when compared with ether and chloroform. There was slight temporary nausea, but no vomiting following the anæsthesia.

The rapid convalescence of the patient shows that the anæsthetic shock was entirely prevented, for it is extremely doubtful whether this patient could have stood ether or chloroform for this length of time.

The case demonstrates the importance of reducing or entirely eliminating the anæsthetic factor.

The surgeon, Dr. H. J. Boldt, informed me that the urine analysis was negative in its results during convalescence. There was also, I am told, a circumscribed area of dulness in the right lung posteriorly. I might also say that during the operation upon the left side the pleura was perforated. Neither occurrence had apparently any effect upon the patient's convalescence, for the temperature and pulse were hardly ever much above the normal. At this writing only ten days have elapsed, and the patient was up the day following operation. Dr. Boldt tells me that this is his usual custom whenever practicable after any operation or anæsthetic, to avoid secondary pulmonary complications, and I must say it is a most commendable one.

While a mixture of gas and oxygen is the safest of all anæsthetics, eliminating the unpleasant features of the gas when used alone, it is, however, the most expensive. In this patient the nitrous oxide used was fifty-five ounces by weight, two hundred and twenty gallons by volume. The oxygen was eleven ounces by weight, sixty gallons by volume; making a total cost of the gases used $7.40. Nitrous oxide is two and oxygen five cents per gallon, as supplied by the dental companies of this city.

As far as I have been able to learn after careful investigation, this is by far the longest period of time in which surgical anæsthesia was ever maintained with nitrous oxide and oxygen. When we consider the age of the patient, the nature and duration of the operation, and the rapid convalescence, the case is certainly remarkable and leaves nothing to be desired.

225 West Forty-fifth Street.

Mild Types of Typhoid Fever.—George Murray Waters questions whether cases of typhoid fever, in which all the symptoms are lacking, can really be called typhoid at all, although conceding that two or three of the symptoms can be absent without invalidating the diagnosis.—*Columbus Medical Journal*, January 5, 1900.

The Laryngoscopic Image.—R. Forns makes a diagrammatic study of the elementary action of each group of the laryngeal muscles (intrinsic). He finds in the special innervation of the crico-thyroid the key to the various clinical appearances found.—*Annales des Maladies de l'Oreille, etc.*, December, 1899.

Abdominal Extravasation of Bile.—B. Poulton reports a case in which the symptoms were so urgent that a laparotomy was performed. The muscles and fasciæ were loaded with bile, and on opening the peritoneum seven ounces of bile were collected. The gall bladder was distended and very large. Continuous irrigation with hot saline solution was carried out, and through incisions made in the right loin and over the pubis large tubes were carried into the lumbar region and the pelvis. No lesion was found in the gall bladder. The author thinks it was a case of perforating ulcer of the common duct, due to impaction of stone.—*The Australasian Medical Gazette*, December 20, 1899.

Excretion of Urinary Water and Urea by Diminished Kidney Weight.—John B. Nash, from a study of three cases and laboratory experiments, concludes that if one kidney be removed, three years later the healthy kidney will excrete more urine than the average excreted by two normal kidneys, and the average amount of urea produced by two healthy kidneys. The same results follow as regards urine if one-half of a kidney be removed, but the urea will be unaffected. After removal of one kidney, the urine excreted during the immediately succeeding seven weeks will be below the average daily amount. The urea will be less than the average for two healthy kidneys. —*The Australasian Medical Gazette*, December 20, 1899.

Immediate and Remote Effects of Nasal Obstruction.—F. R. Reynolds states that by the successful treatment and permanent relief of nasal stenosis, many diseases are prevented, relieved, or cured. Among these are anæmia, marasmus, hay-fever, asthma, and laryngismus stridulus. Reflex cough may be due to hypertrophic rhinitis. Also gastralgia, cardiac palpitation, neuralgia of the trigeminus, scotoma, migraine, cephalalgia, ciliary neuralgia, vertigo, photophobia, neurasthenia, spasmodic cough, spasm of the glottis, frontal and supra-orbital headache may all have their origin in an exciting nasal focus. Emphysema and bronchitis often accompany nasal stenosis. Nasal stenosis not rarely has a deleterious effect on the ears. —*The Medical Age*, January 25, 1900.

Remarkable Tolerance of the Young Child for Opiates.—Borde relates his experience in the use of opiates for young children which seems to be at variance with the generally accepted views on the subject. He gives a summary of his treatment of sixty-four cases, the patients ranging in age from one month to twenty-five months. He declares that he has never observed signs of intoxication from opium—that is, coma, contraction of the pupils, cessation of urine, anorexia, arrhythmical respiration, flushed face, convulsions, etc. Borde uses opiates most frequently in fetid diarrhœa. His successful experience has been too wide to be called accidental. He has used four different preparations: first, the syrup of diacodium, which he uses no longer on account of its feebler activity; second, laudanum, which he has now ceased to use because its activity can be modified by its age; third, syrup of thebaine; fourth, syrup of morphine, which he prefers because it contains only one alkaloid, and because its standard does not vary. He believes that the child has a much greater tolerance for opiates than the adult.—*Journal de Médecine de Bordeaux*, December 31, 1899.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, March 3, 1900.

REGULATION OF THE PRACTICE OF MIDWIFERY AND PROVISION FOR THE LICENSING OF MIDWIVES IN NEW YORK CITY.

AN assembly bill has recently been introduced with the above object in view. The bill in question seems to present several objectionable features, and could be greatly improved by much judicious revision. Probably were a vote of the members of the medical profession throughout the State taken as to the necessity or desirability of licensing midwives, the consensus of opinion would be against such a course.

A very large number of physicians think that the licensing of midwives would be by no means a step in the right direction, but rather hold that a parturient woman is likely to receive more beneficial treatment at the hands of a skilled medical practitioner than if placed in the charge of a midwife. If, however, a bill of this description is to come into force, at any rate it will be well to have as satisfactory a one as is possible. The bill in its present form does not fulfil these conditions. Exception may be taken to its first section, in which it is provided that the mayor of the city of New York shall appoint the examining-board. Surely such an appointment should be left to the discretion of the Medical Society of the County of New York. Another provision of the bill which will decidedly meet with the disapprobation of the medical profession is that a board of examiners should be appointed to serve without compensation. Physicians already perform more than their fair share of gratuitous work, and why they should be required to fill posts of this nature for "love and good-will" alone is a thing, in the words of the immortal Lord Dundreary, "no feller can understand." Again, grave objections must be brought against that portion of the bill which provides for a board of examiners for New York City only. Physicians in all parts of the State should insist upon this clause being struck out or altered. The Medical Society of the State of New York has always strongly opposed bills to create examining-boards for midwives in separate cities and counties, and has insisted, and rightly so, that if midwives are to be licensed the practice should include the whole State. If this provision were allowed to become law, an extremely awkward precedent would be established: other cities in the State would probably follow suit, and would in the long run bring about a state of chaos.

There has been but little convincing testimony forthcoming that the midwives bill is called for. On the contrary, the mass of evidence tends to point in the opposite direction. Doubtless the services of a midwife who has undergone an examination testifying that she possesses a certain amount of experience and skill would be preferable to those of one who has been put to no such test. But, on the other hand, the fact must be plain to the veriest tyro that even a licensed midwife cannot be expected to grapple with all the complications which may occur, with the confidence of a qualified medical practitioner. In the end it will assuredly be found cheaper to employ skilled attendance, and when the public has grasped this truth the present class of ignorant midwives will in the natural course of things pass away.

The duty of medical journals is to bring the minds of the community at large to a realization of this fact.

MANAGERS AND PHYSICIANS.

IT is proposed to establish a hospital for the care of indigent crippled and deformed children who may have resided in this State for a period of not less than a year, and for that purpose a bill has been introduced into the House of Assembly. The aforesaid hospital is to be located within a reasonable distance of the city of New York.

The object is most meritorious, and will without doubt prove a great boon to the many unfortunate little ones who by reason of their infirmities are a burden on their people, and who live in too many instances a life of the utmost misery amidst the dirt and vice of this great city. At the same time the bill contains certain clauses which are deserving of sharp criticism. Section 3, after detailing the duties of the managers, reads as follows: "They shall not receive any compensation for their services, but shall receive actual and necessary travelling and other expenses." Section 5 commences thus: "All the surgical and medical officers of the hospital shall render their services gratuitously," and ends with these words: "For the first two years the attending surgical and medical officers shall provide their own surgical operating-instruments."

Now there can be no particular objection to the managers receiving actual and necessary travelling and other expenses, but why should the surgical and medical officers be expected not only to give their services, but should also be required for the first two years to provide their own surgical operating-instruments? Is it because the duties of the managers are so much more onerous than those of the medical staff that this seemingly unfair discrimination is made? Impartial, unprejudiced persons, who are familiar with the manner in which hospitals in this State are conducted, are of the opinion that the contrary is the case. This is without doubt the fact, and it is the fault of the members of the medical profession themselves that they do not receive adequate compensation for the work they perform. If the physicians and surgeons of this State were one and all to insist—barring very exceptional circumstances—upon being paid for services rendered, the cause of charity would not suffer, and an excellent example would be set to their professional brethren in all parts of the country. The medical profession throughout the world might with advantage take to heart and act upon the good old Bible precept, "The laborer is worthy of his hire."

STATUS EPILEPTICUS.

The symptomatology and pathology of status epilepticus are deservedly receiving much attention at the hands of neurologists. The status in epilepsy is fairly well recognized now to be the acme or climax of the disease; that is, given the greatest number of contributing causes, the epileptic is foredoomed to die of the status as the maximum development of the disease. Certainly chance plays no part in the production of status.

Throughout all the present-day definitions of status epilepticus, we find that the constant factors of rapidly repeated seizures and the progressive deepening coma are always included as the essentials of the condition. There is also a marked elevation in the fever, pulse, and respiratory curves. Some still hold that status is seen only in certain kinds of epilepsy; but by far the greater number of authorities maintain the more logical ground that the condition may occur in all epilepsies. An interesting point is disclosed by recent investigations, as there appears to be a necessity for reviving the old theory of cortical heat centres (Eulenburg and Landois) to explain the high temperature in status epilepticus composed entirely of psychic attacks. The fever curve of status still remains mysterious, although it is generally in direct ratio with the severity and number of epileptic convulsions. Inasmuch as this rule is not always true, there are evidently latent factors in heat production in the epileptic paroxysms, which are not referable to the muscular convulsions. The understanding of the anomalous fever curves in status will probably rest for ultimate solution upon its etiological pathology. After all, the enigma of the fever curve is not more difficult of solution than the loss of consciousness in isolated convulsions of epilepsy proper. The length of time after the disease of epilepsy begins and the time when status will occur is a point of great practical importance to all physicians. Recent statistics seem to prove that epilepsies developed in later life have status in a shorter period of time than when the epilepsy is contracted in early life. However this may be, it is certain that the disease of epilepsy in the majority of cases must be very well established before status will supervene. Epileptics may never have more than one status period, or may have six or seven, although the latter number is quite rare. Cases are not unknown in which patients have recovered from status and also from the epilepsy proper; although it is now generally conceded that status is the severest manifestation of epilepsy, and but few patients ever recover from their disease when status has once occurred.

The influence of menstruation and pregnancies upon the production of status in epileptic women is *nil*. It is as infrequent a clinical experience to see true status develop from the menstrual period as it is common to see serial attacks of major hysteria at such epochs. This fact alone aids one much in the differential diagnosis.

The immediate cause of status is still as indefinite as that of epilepsy proper, and the solution of the problem probably rests upon the discovery of the pathology of the affection and the modifying agencies of the individual's resistance to the progress of the disease. Its pathology, beyond a vascular and cellular degeneration of the cortex, is still obscure. Oftentimes the vascular and cellular degeneration is really a result rather than a cause of the status. The actual onset of status does not differ from the beginning of serial attacks, and serial periods, without status, are frequently termed aborted or pseudo-status. Careful attention to these periods frequently delays the presence of true status epilepticus in the individual patient. The gradual, step-like advance of the grave symptoms is the cardinal factor in forming a prognosis of status.

The advance of our knowledge of treatment of status is not great. A significant fact of the futility of medicinal treatment is seen in that all plans of medication are of service in isolated cases. The percentage of recoveries remains about sixty or seventy in spite of improved methods of treatment. In the medication of status it should always be borne in mind that that which is indicated for the convulsive stage is contraindicated for the stuporous stage, and that the administration of large doses of chloral, uncombined with other drugs, has come to be considered as dangerous medication, in the light of depressing effects obtained from chloral upon weak hearts. Notwithstanding the frequent abscess formations from hypodermic bromide medication, this line of treatment is steadily growing in favor in the severest cases of status. Good general nursing is nowhere more needed than in giving proper care to epileptics suffering from status, either in their own homes or in special hospitals for this disease.

SCIENTIFIC PREFERMENT IN CUBA.

Complaint is made in the February number of the *Archivos de la Policlinica* of Havana, concerning the manner in which medical appointments are made under the present régime. Formerly (that is, under Spanish rule), our esteemed contemporary says, scientific merit was the means by which posts of honor and profit were obtained, and medical men were thereby stimulated to study and to conduct original investigations. Under this stimulus the laboratory of the *Crónica Médico-Quirúrgica* and the Free School of Medicine were established, the attendance at the meetings of medical societies was large and enthusiastic, and the first insular medical congress was held. Now, however, desirable positions are obtained through personal friendships, and there is no necessity for superior knowledge nor any reward for study. At first, the *Archivos* says, these appointments were made for political merit, and to this no objection is made, since the country owes its existence to the army, but now, it complains, not the most fit among the politically deserving, but the most friendly to the new powers are selected. And recently, indeed, even political merit no longer counts, but only personal favor. Influence is now the sole recommendation to preferment. We trust the condition is not universally so bad as that, and that one or two specific instances have led our esteemed contemporary to a generalization. But there should not be even one such instance, and certainly the present military governor of the island, who is himself a scientifically trained medical man and no friend of place hunters, does not countenance such abuses. The medical men of Havana should take their complaints to General Wood, for he will heed them.

News of the Week.

Philadelphia County Medical Society.—At a stated meeting held February 14th Dr. Thomas J. Mays exhibited a number of patients with phthisis treated with injections of silver nitrate. Dr. B. Franklin Stahl presented a communication entitled "Copy the Formula on the Label." Dr. John H. Gibbon presented a communication entitled "Rupture of the Plantaris (Lawn tennis Leg)."

College of Physicians of Philadelphia: Section on General Medicine.—A stated meeting was held February 12th, when Dr. Frederick A. Packard read a paper entitled "Diet in Typhoid Fever." He pointed out that the most important cause of death in typhoid fever is the intoxication or the asthenia, and he analyzes the suggestions that have been made by various clinicians to enlarge the customary diet employed in this disease with the object of averting the dangers arising from these conditions. While he has himself not gone beyond the conventional diet as yet, he proposed to do so as soon as a suitable opportunity offered. He laid emphasis upon the administration of water in generous amounts. Dr. John H. Musser read a paper entitled "The Use of Stimulants in Typhoid Fever." He pointed out that alcohol is not required in the sthenic cases, and is needed in the asthenic cases only when the tongue becomes dry, the secretions are diminished, the urine is deficient, and muttering delirium, with picking at the bed-clothes, is present, and the pulse is soft and feeble, and the sounds of the heart are weak. Dr. James M. Anders read a paper entitled "The Use of Intestinal Antiseptics in Typhoid Fever." He pointed out that in accordance with present conceptions of the disease little can be hoped for from the administration of antiseptics in the treatment of typhoid fever. It is his custom when the diarrhœa is not present to administer calomel at the outset, and when meteorism is present and the character of the intestinal evacuations furnishes the indication, to administer salol in doses of gr. iii. at varying intervals, and occasionally to make antiseptic injections into the bowels. Hydrochloric acid is useful both as an antiseptic and as an aid to digestion. Dr. James Tyson said that as milk contains all of the necessary elements of food, and that, as in the case of infants, it seems designed by nature as a suitable article of diet, it appeared to him the most available form of food in cases of typhoid fever. So many of the unpleasant symptoms previously observed have disappeared since the more general adoption of the Brand method of treatment that the need for stimulants has been greatly diminished. So, too, a better appreciation of the nature of typhoid lever has removed the indication for intestinal antiseptics. Dr. Judson Daland stated that it is his custom to supply fluid to the body by means of rectal injections of salt solution. He pays especial attention to the condition of the mouth. Dr. B. F. Stahl stated that milk can be made more available as a food in the management of febrile conditions if more attention is given to variations in its preparation; for instance, by greater dilution the dangers from the formation of large curds is easily obviated. Dr. H. A. Hare stated from personal experience that he felt it desirable to feed typhoid-fever patients more liberally than has been the custom in the past. In his own practice patients are permitted to have from two to four eggs, soft boiled, daily, and with the approach of defervescence also corn starch and tenderly boiled rice. Strychnine should not be given for too long a time, as it is a cardiac stimulant and may cause abnormal cardiac activity.

Antirabic Inoculations in Berlin.—Three hundred and eighty-four persons bitten by mad dogs and cats were treated during the past year in Berlin by means of antirabic inoculations. Three hundred and seventy-eight of these recovered, and three of the six who died were already suffering from rabies when treatment was begun.

Philadelphia Pediatric Society.—At a stated meeting held February 14th, Dr. A. A. Eshner presented a case of mitral obstruction and pulmonary obstruction, occurring in a girl nine years old. Dr. J. P. Crozer-Griffith presented a case of congenital heart-disease, with great cyanosis and clubbing of the fingers, in a boy of about six years. Dr. G. G. Davis presented a case of double congenital dislocation of the hips in a girl five years old, in whom permanent reduction had been effected upon one side at the age of three and one-half years, and after other measures had failed an artificial acetabulum was created at the age of four years on the other side, with retention of the head of the femur in the new socket. The previously marked lordosis had quite disappeared, and there was but little shortening on the side operated on. Dr. J. P. Crozer-Griffith presented a case of cerebral diplegia with choreiform movements, and also a case of stenosis of the larynx in the course of typhoid fever. Dr. A.

M. Seabrook read the report of a case of hemorrhagic purpura in a new-born infant. Although the umbilical wound had healed smoothly, hemorrhage occurred from the umbilicus on the fifth day, requiring the application of hare-lip needle ligatures. At the same time large oval ecchymotic spots appeared in numerous situations. The needles were kept in place for sixty hours; the ligatures came away in a week, and recovery ensued. Dr. F. A. Packard read a paper entitled "A Brief Note on Kernig's Sign in Infants," relating cases of meningitis in children, in which extension of the leg upon the flexed thigh could be effected with the patient in the sitting posture.

A State Hospital for Inebriates.—It is stated that a bill will be introduced into the New York legislature during the present session to establish an institution for the treatment of the victims of alcohol and drug addiction. The bill provides for the appointment by the governor of a board of managers who will receive compensation during the time they are engaged in making plans for the institution. After it is ready for the reception of inmates, the managers are to serve without pay, each for a term of three years. The institution is to have accommodations for three hundred inmates. Incurables will not be admitted. Inebriates may be committed for terms of five years, but it is purposed to have a parole system similar to the one now in use at the Elmira reformatory. Commitments will be made by magistrates, although persons seeking to enter for treatment will be accepted when there is room for them. The cost of maintenance of inmates committed by magistrates will be charged against the counties from which they have come.

Limiting the Output of Doctors in Russia.—The Russian government has grappled with the question of the over-production of medical practitioners in a drastic manner peculiarly its own. By a recent decree of the minister of education the admission of first-year students by the several medical faculties throughout the empire is restricted to a fixed number. The University of Moscow is limited to 250, Kieff to 200, Charkow to 175, Dorpat to 150, Warsaw to 100, Tomsk to 120, and Kasan to 100. The total number of first-year medical students in the dominions of the Czar must, therefore, not exceed 1,095. This number does not include the students of the St. Petersburg Medico-Military Academy, which is allowed to admit 250 first-year students.—*British Medical Journal.*

Prevention of Venereal Disease in Norway.—Dr. C. R. Drysdale writes to the *British Medical Journal* regarding a bill recently introduced into the Norwegian Storthing. This bill was drawn up by a committee of statesmen and physicians, and was presented for discussion to the members of the Brussels Congress. Many of its sections, the writer says, are quite unsuited to a country so little accustomed to paternal government as the United Kingdom, and we may add the United States, but he thinks the following sections might serve as suggestions for some future bill to be drawn up for the United Kingdom: "Section XI.—Every practitioner who examines a person affected with a venereal disease is required to inform his patient of the contagious nature of his disease; and at the same time must seriously explain to the patient his legal and moral responsibilities, in case he shall communicate the disease to another person, or expose others to contract it from him. The practitioner must, above all, call the attention of the patient to the danger of contagious relapses of his malady; and of the consequences of it to his children, and at the same time inform him that he should frequently have himself examined in case such a relapse may occur. [The practitioner must also tell the patient what means he should employ to prevent such contagion to others.] The Minister of Public Health may cause printed instructions to be drawn up, and given by the practitioner to his venereal patients. Section XIV.—Every practitioner who treats a venereal patient and who knows that the patient by his conduct is exposing others to contagion, must immediately make this known to the president of the health commission."

Corresponding Members of the Academy of Medicine of Paris.—At the session of the Paris Academy of Medicine, held January 30th, Drs. Kaposi, of Vienna, Erb, of Heidelberg, and Hansen, of Bergen, were elected foreign correspondents.

An International Congress of Medical Electrology and Radiology will be held in Paris the week previous to the meeting of the International Medical Congress, from July 27th to August 1st. Those desiring to take part in this congress are requested to communicate with Dr. E. Doumer, secretary-general, 57 Rue Nicholas-Leblanc, Lille.

Tuberculosis in Denver.—According to the annual report of the Denver board of health, there were 536 deaths from tuberculosis in that city during 1899. In 1898 there were 505 deaths from this disease, and in 1897 489. Only 58 of the deaths in 1899 were of persons who had contracted the disease in Colorado, this comparing favorably with the 99 fatal cases of tuberculosis acquired in the State in 1898, and 88 in 1897.

Dissatisfied Homœopaths.—The members of the homœopathic and eclectic State medical examining boards of Pennsylvania are dissatisfied with the distribution of fees under the act of assembly providing for the examination of applicants for license to practise medicine. Each applicant pays a fee of $25, and the fees, less expenses, are distributed among the three boards. As many applicants appear before the regular board, representing the Medical Society of the State of Pennsylvania, and comparatively few before the other two boards, the former have not complained of their remuneration, while the latter are correspondingly unhappy.

The Paris Congress.—The Compagnie Générale Transatlantique announces a reduction of ten per cent. on tickets from New York to Paris to members of the International Medical Congress. The French railway lines offer a round-trip ticket for a single fare. The secretary-general of the congress, Dr. A. Chauffard, 21

Rue de l'École de Médecine, Paris, has arranged to provide early applicants with lodgings at the rate of 5 francs a day. This includes light and service, but not meals.

The American Medico-Psychological Association.—The meeting of this society in Richmond, Va., will be held May 8th, 9th, 10th, 11th—not May 1st, 2d, 3d, 4th, as heretofore announced. The change in date is made to enable members to attend the Congress of American Physicians and Surgeons in Washington, May 1st to 4th.

Vinegar as an Antidote to Carbolic Acid.—Dr. Edmund Carleton of this city requests that proper credit be given to him for the discovery that vinegar will relieve both internal and external burns from carbolic acid. We give it to him with pleasure, but must add that the same fact was noted in *The Lancet* four years ago (p. 255, i., 1896).

"The Medical Examiner," a journal hitherto devoted to the interests of medical examiners for life insurance and others, and ably edited by Dr. George W. Wells, is to enlarge its field of usefulness. The editor says that, as every part of medicine bears upon the duration of life, he will henceforth admit to his columns articles upon any medical subject, and the title of the journal is accordingly enlarged to *The Medical Examiner and General Practitioner.*

A Mysterious Dog Malady in England.—A correspondent of *The Medical Press and Circular* suggests that the plague may be existent at present in England. This surmise is based upon the fact that some six or eight months ago there appeared at Southampton a disease which attacked dogs, and proved so fatal and infectious that in a short space of time the town was practically cleared of its canine population. Since then the disease, which appears to be of a highly specific nature, has spread slowly but surely over many parts of the United Kingdom. Deaths from this epidemic are occurring at the present time in London, and veterinary surgeons are now everywhere alert as to its occurrence. The points suggestive of plague are the invasion of a seaport town, where dogs might easily become infected through ship rats, and the fatal nature and the high degree of infectiousness of the malady. On the other hand, as our contemporary remarks, it is hardly likely that, if plague had really attacked so widely domesticated an animal, the contagion would not quickly have been communicated to man.

Medical Expert Testimony.—A good story is republished in *Law Notes* from the reports of the supreme court of California. A woman named Doolin brought an action against the Omnibus Cable Company for damages for injuries alleged to have been received by her in the derailment of one of the defendant's cable cars. Some months before the trial an examination of Mrs. Doolin was made by six physicians, three appearing in her behalf and three for the defendant, for the purpose of ascertaining her physical condition. At the trial several of these physicians testified that they had ascertained during the examination that she was suffering from a tumor, either ovarian or uterine, and of about the size of a cocoanut; but they differed as to its precise location. As to the existence of the tumor there seemed to be no dissent. The family physician of the plaintiff testified that the tumor had increased in size until it had become about four times as large as when the examination was made. The defendant contended that plaintiff's ailments were caused by the tumor and not by the accident of the cable car. On the other hand, the plaintiff sought to show that the tumor was the result of the accident. Ten days after the trial Mrs. Doolin gave birth to a child at full term. On the appeal each side admitted that such was the fact, and that she had not been suffering from a tumor at all.

Christian Science and Life Insurance.—There is a case now before the supreme court of Connecticut in which the question is to be decided whether a life insurance company can be compelled to pay a claim when a Christian Science policy holder dies after having refused all medical treatment.

A Privat-Docent Expelled from the University of Berlin.—Dr. L. Arons, a privat-docent in electricity at the University of Berlin, has been expelled by the State authorities because he is a member of the Social-Democratic party. The senatus of the University was requested to do this some months ago, but refused, so the government has taken upon itself to expel him.

The Gonococcus as a Therapeutic Agent.—A correspondent of *The Medical Press and Circular* says that one of the best remedies with which he is acquainted for habitual excessive indulgence in alcoholic beverages is the gonococcus. Over and over again, he says, he has failed to induce patients with this particular weakness to control their appetite for alcohol. Promises of reform were made only to be broken. Then they contracted gonorrhœa, and forthwith, without any pressure, for three long months at least, they forewent their tipple, and recovered the strength of will which they had lost. He says he could point to a number of cases in which the drunkard's progress has been summarily arrested by an intercurrent attack of gonorrhœa with the most satisfactory results in respect of his after life, and he thinks it is really open to question whether in refractory cases this treatment might not offer an alternative to seclusion in a home for inebriates.

The Long Island Hospital.—The board of managers of the Long Island State Hospital recently adopted resolutions of protest against the failure of Governor Roosevelt to reappoint Dr. Truman J. Backus as a member of the board. After a preamble expressing regret that the governor did not reappoint Dr. Backus according to promise, the board resolved: "That the method of procedure through which Dr. Backus was retired from the office of manager of this board is a disappointment and discouragement to its members, and should be to all honorable and manly State officials, who gave their time and energies in furthering the philanthropic obligations of the State to its wards, without reward of any kind whatever, except that which comes through the pleasure of personal identification with good works and the promptings of a right conscience. Against the continuance of such methods this board respectfully and earnestly protests." Copies of the resolutions were sent to Governor Roosevelt, to the Commission in Lunacy, and to Dr. Backus.

The Medical Census of Great Britain.—The recently issued Medical Directory contains the names of 35,651 qualified medical practitioners, an increase of 534 over the number of last year. In the London list, however, there is a falling off of 15 names. The number of surgeons in the army, navy, and Indian medical service is larger by 177 than it was a year ago, despite the vigorous protests against unfair treatment of army surgeons by the line officers.

A Judicial Opinion on Medical Honesty.—During the trial of a case of assault before one of the New York police magistrates recently, a certificate from a physician was presented to the effect that one of the parties to the case was unable to appear in court. Then, "Oh, these doctors' certificates don't amount to anything," the magistrate is reported to have exclaimed. "You can get them for ten cents over in the Essex Market district, and I guess it is just as easy to get them over here. I won't recognize any certificates except those from hospitals or hospital doctors."

A New Harlem Hospital.—The department of charities has determined to build, as soon as possible, a new Harlem hospital, and ground will be broken for it in the spring. It is thought a site will be purchased in Lenox Avenue, between One Hundred and Thirty-fifth and One Hundred and Thirty-sixth streets, embracing twenty-six city lots. The hospital, when completed, will cost, inclusive of the plot, in the neighborhood of $500,000, and will be one of the most attractive public hospitals in the city. At first it is probable that only one section will be built. An effort is being made to induce the department to put a part of the new hospital in charge of homœopathic physicians.

Damages Claimed for Antenatal Injuries.—The supreme court of Illinois has recently handed down a decision in a peculiar case. It was that of an infant who claimed damages for a deformity alleged to have resulted from injury to the mother before its birth. The mother, while pregnant, was injured in an elevator accident at St. Luke's Hospital, Chicago, her left leg being caught and crushed. When the child was born, his left leg was deformed. The hospital authorities settled with the woman for her injuries, and then she brought suit in the child's name for $50,000 damages for the deformity, which it was claimed was due to the same accident. The court dismissed the suit on the ground that at the time of the accident the child could not be credited as a separate being, capable of sustaining an action independent of the mother.

Filtering Croton Water.—A resolution was introduced at a recent meeting of the New York board of aldermen, requesting the board of public improvements to inform for Municipal Assembly whether a filter could not be arranged in the Croton aqueduct which would prevent the water from getting dirty and muddy.

Dr. Henry E. Muhlenberg has been elected mayor of the city of Lancaster, Pa.

Philadelphia Polyclinic.—Dr. Jay F. Schamberg has been elected professsor of diseases of the skin in succession to Dr. J. A. Cantrell, resigned.

Munificent Bequest.—By the death of the widow of the late Benjamin D. Maxham the sum of $100,000 will revert to the New Jersey Training-School for Feeble-Minded Children at Vineland.

Yellow-Fever Ships.—Several vessels have recently arrived here from Santos infected with yellow fever. What with the plague and the yellow fever it is becoming the rule for coffee ships from Santos to be kept in quarantine on their arrival at this port.

Measles on Randall's Island.—The Infants' Hospital on Randall's Island has been quarantined on account of an epidemic of measles that threatened the children. Ten cases of the disease have been discovered, but all have been isolated, and the epidemic is now apparently under control. Foundlings will be sent to the New York Foundling Asylum until the measles have disappeared.

Opposition to a Pest-House.—Smallpox having recently broken out in New Rochelle, the health authorities took measures for the erection of a pest-house on the outskirts of the city. Farmers in the neighborhood, however, opposed the placing of the hospital near their homes, and when they found that their protests were unavailing they organized a band and drove away the builders with threats of violence.

Defeat of the Barber Licensing Bill.—The Brennan bill, providing for the appointment by the governor of a State barbers' examining-board, also requiring the examination and licensing of barbers and the inspection of the sanitary condition of their shops, was killed in the Assembly last week when it came up on the order of second reading. It was moved to strike out the enacting clause, which motion was carried by a vote of 70 to 42.

A Crowded Hospital.—Bellevue Hospital has had so many calls on it of late that its facilities have been taxed to the utmost. A large number of patients were transferred one day last week to the City Hospital on Blackwell's Island. Before the transfer there were eight hundred and twenty-eight patients at Bellevue. The hospital accommodates eight hundred and fifty persons, but sixty of the cots are for insane or alcoholic patients. The congestion was due to the many cases sent from other hospitals to Bellevue.

Liberal Bequests.—By the will of Elizabeth W. Baker, who died recently at Philadelphia, two bequests of $5,000 each are made to such hospitals as her executor, Dr. George Fales Baker, shall select, her own preference being in favor of the Pennsylvania or Presbyterian for the one, and the University Hospital for the other, for the endowment in perpetuity of five free beds.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending February 24, 1900. February 16th.—Pharmacist R. Waggener granted sick leave for four months. February 17th.—Assistant Surgeon J. R. Murphy appointed assistant surgeon. February 19th.—Assistant Surgeon Karl Ohnesorg ordered to temporary duty at the Naval Academy. February 21st.—Medical Director W. G. Farwell commissioned medical director from January 22, 1900. Medical Inspector D. N. Bertolette commissioned medical inspector from January 22, 1900.

The Plague is thought to have been overcome in Honolulu; at least there had been no cases reported for ten days prior to February 16th, the date of the latest advices. The disease has appeared elsewhere in the islands, however, news of seven deaths in Kahului, on the island of Maui, and of one at Hilo, on the island of Hawaii, having reached Honolulu. The same energetic measures were instituted at Kahului that had been successful at Honolulu. Chinatown, which was found to be in a fearful sanitary state, was burned to the ground, and two hundred and fifty Orientals were put in the detention camp. The sheriff organized a posse to search all persons who had been in Chinatown within the period of infection, and on the plantations a regular system of inspection was adopted.—A despatch from Aden, under date of February 23d, states that six cases of the plague and one death have occurred there. Drastic measures have been taken to prevent a spread of the disease. The infected districts have been isolated. Another case of the plague has been discovered in Sydney, N.S.W., and many persons who had been in more or less intimate contact with the victim have been quarantined.

The Author of the "Gold-Cure" Treatment Dead.—Dr. Leslie E. Keeley, who won fame of a certain kind and a large fortune through the exploitation of the "gold cure" treatment of inebriety, died of heart disease at Los Angeles, Cal., on February 21st. He was born in St. Lawrence County, N. Y., about sixty-eight years ago, and was graduated from the Rush Medical College, Chicago, in 1864. He entered the army as acting assistant surgeon upon graduation and served until the close of the war. He then settled in Dwight, Ill., where he practised medicine for many years in a conventional way. A few years ago he announced that he had discovered a remedy for the cure of alcoholic addiction, and opened a sanatorium for the reception of patients with this habit. Later he closed this institution, saying his treatment was not perfect, and he wanted to discover something to counteract the influence of the bichloride of gold on the system. After two years he resumed his treatment, and though his claims were disputed and his theories ridiculed, he prospered financially, and soon a company was formed for the establishment of "gold-cure" institutes in various parts of the county. He owned a half interest in this company, and is credited with having made more than a million dollars while the gold-cure boom lasted.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended February 24, 1900:

		Cases.	Deaths.

Obituary Notes.—DR. ERNEST BREWSTER SANGREE, late professor of bacteriology and pathology in the department of medicine at Vanderbilt University, Nashville, Tenn., died at the home of his father, in Harrisburg, Pa., on February 23d. Dr. Sangree was also bacteriologist of the State of Tennessee prior to relinquishing the professorship of Vanderbilt University to accept a similar place in the University of Illinois. He was thirty-six years old, and was a graduate of the Medico-Chirurgical College of Philadelphia in 1889.

Dr. Joseph M. Creamer died of pneumonia at his home in Brooklyn, N. Y., on February 23d, at the age of forty-nine years. He was a graduate of the medical department of the New York University in 1873. He served a term as coroner in 1892.

Dr. Henry B. Moore died at Colorado Springs on February 21st, of pneumonia. He was born in Maine, and was graduated from the Jefferson Medical College in 1886. He served a term as interne at the Blockley Almshouse in Philadelphia, and practised for a while in this city, but was obliged to remove to Colorado on account of his health.

Dr. Andrew R. Wright, a prominent homœopathic physician of Buffalo, N. Y., died in Chicago on February 25th, at the age of seventy-four years. He was born at Crawford, N. Y., and studied at the Buffalo Medical College and in Paris, but obtained his degree from the Homœopathic Hospital College in Cleveland, O., in 1858. In 1898 he was president of the American Institute of Homœopathy.

Dr. James L. Watson died in Brooklyn on February 22d, of cardiac disease following influenza. He was born in 1830 and was graduated in medicine in 1857. He was the last surviving member of the old City Guard of Brooklyn, which was merged into the Twenty-third Regiment. He served as surgeon in the civil war, and was for some time surgeon-general of the Grand Army of the Republic.

Dr. William Edward Walmsley died at his home in Brooklyn on February 25th, at the age of forty-five years. He was born in Rochester, N. Y., and was graduated from the medical department of the New York University in 1877.

Dr. I. B. Lathrop died at Springville, Pa., on February 20th. He had been engaged in the practice of medicine in Susquehanna County for nearly fifty years.

Dr. I. F. Schminkey died at Gratz, Pa., on February 19th, at the age of sixty-seven years. He was at one time a member of the State legislature.

Vibration as a Hypnotic and Anæsthetic.—B. F. Ward advances the theory that narcosis and anæsthesia may be produced by vibratory force, and that the vibration, in order to exert its specific effect upon the nerve centres, must be uniform and rhythmic, and to reach its greatest intensity the vibratory wave must gradually and steadily increase in force. The writer says it would be impossible to devise any appliance which would so fully meet these indications as the relations that exist between a steel rail and a revolving car wheel, because the vibratory thrill will begin to be faintly delivered while the train is still many miles away, and with every revolution there will be a uniform and perfectly rhythmic increase in the force of the vibratory wave. He suggests that it would be possible to mechanical skill to devise a metallic operating-table with wheels run by electricity against rails attached to the under surface that would impart to the table and the subject thereon a vibratory force exactly similar to that which the rail receives from the revolving wheel and equally potent, and that a perfect anæsthesia might thus be secured as free from danger as natural sleep.—*Journal of the Mississippi State Medical Association*, February, 1900.

Progress of Medical Science.

Journal of the Amer. Med. Association, Feb. 24, 1900.

Treatment of Typhoid Fever. — Frank Billings says that at present the specific treatment of typhoid fever is on trial, although the success so far attained gives us hope of still better results. He sums up the methods of treatment under the heads of efficient nursing, a proper diet, and the elimination of the toxins, and concludes that for the latter purpose hydrotherapy is best.

Treatment of Typhoid Fever in Private Practice.—William E. Quine discusses this subject under the heads of prevention, general management, diet, water, medicines, and hydrotherapy. The writer says that although it be admitted that the Brand treatment effects a saving of life in hospital practice amounting to six or seven per cent., its use in private practice must necessarily be of slow growth.

Treatment of Medical Complications of Typhoid Fever.—George W. Webster discusses the treatment of thrombosis, of respiratory complications, and of pain as among the possible problems for the physician in typhoid fever. He says that most important of all is the support of the right heart. As soon as this begins to flag, we must make use of strychnine, digitalis, ammonia, oxygen, camphor, or caffeine.

Tobacco Amblyopia.—Francis Dowling gives the results of some recent examinations made to determine the influence of tobacco on vision among the employees of the tobacco factories of Cincinnati. He thinks that a tobacco-laden atmosphere is not enough to produce poisoning so far as the eyes are concerned, but that these symptoms are the result of smoking or chewing.

Electro-Cautery in Affections of the Lids and of the Cornea.—Flavel B. Tiffany enumerates the many affections of the lids and cornea in the treatment of which he has found the electro-cautery a valuable agent. Among these affections may be mentioned ulcers and fistula of the cornea, phlyctenular keratitis, pannus crassus, trachoma, keratoconus, staphyloma, ectropion, entropion, distichiasis, and trichiasis.

Craniectomy for Epileptiform Seizures and Grave Mental Disturbances following Head Injury without Apparent Fracture.—H. Reineking reports this case as illustrating what violent disturbances may follow comparatively slight traumatisms of the head. Operation was followed by immediate recovery.

Silver Catgut and How to Tie it.—Eduard Boeckmann says that although several improvements must be made before we can speak of ideal catgut, still the catgut impregnated with metallic silver is so nearly perfect that it can successfully take the place of all other kinds of material for sutures and ligatures.

A Sulpho-Salt of the Aliphatic Creosote-Esters and its Therapeutic Usefulness.—Heinrich Stern reports cases of diabetes insipidus, diabetes mellitus, and chronic ulcerative phthisis in which eosolate of calcium was employed with varying results.

Scarlatina and Scarlatinous Sore Throat.—W. J. Class reports in detail three cases in which cultures from the secretion of the throat and the blood showed the presence of the micro-organism described in the Medical Record, vol. lvi., pages 330 and 513.

Cremation.—Robert Marsena Stone thinks that very soon cremation will be adopted by the educated class in all communities, and argues for the æsthetic as well as the hygienic virtues of this method.

Food and Drink.—In this article Elmer Lee discloses the secret of long and healthy life, namely two meals a day and profuse water drinking.

Philadelphia Medical Journal, February 24, 1900.

The Etiology of Sydenham's Chorea.—Joseph Collins and I. Abrahamson analyze one hundred cases. No disease except rheumatism seems to be an etiological factor. The exciting cause is psychical trauma or physical exhaustion, very seldom gastro-enteric irritation or eye-strain. Mental symptoms were noted in fifty-four of the cases studied.

Subhyoid Pharyngotomy for the Removal of a Malignant Growth of the Larynx.—F. J. Lutz reports this operation in a man, aged seventy-three years. The patient survived a month, the dyspnœa and dysphagia from which he had suffered being entirely relieved.

Certain Effects of Benzoic Acid upon the Urine.—William W. Ashhurst finds benzoic acid has an inconstant diuretic action, diminishes the acidity of the urine slightly, retards or prevents alkaline fermentation, and inhibits the growth of micro-organisms.

Inter-Scapulo-Thoracic Amputation.—William D. Hamilton reports a case of sarcoma of the shoulder following repeated injuries in a man, thirty-two years old. Amputation of the upper extremity with clavicle and scapula was successfully performed.

The Resuscitation of Apparently Dead New-born by Laborde's Method.—Francis Eustace Fronczak reports four cases of resuscitation of asphyxiated infants by rhythmical traction of the tongue.

A Case of Successful Symphyseotomy.—Joseph B. De Lee reports a case in a secundipara, about thirty-one years old.

New York Medical Journal, February 24, 1900.

The Benefits of Balneotherapy in the Treatment of Chronic Rheumatism and Gout.—H. H. Schroeder prefers the spa with its change of climate and other stimulating environments to the average hydropathic institute with its sick and grumbling inmates, and describes a place in the Rocky Mountains which in his judgment offers ideal advantages. The author then discusses the details of treatment, stating that it is well to warn the patient that an increase of joint pains is liable to occur during treatment, but that as a rule the pain soon ceases.

The Treatment for Hypertrophy of the Inferior Turbinated Bone.—E. Harrison Griffin precedes operation by the use of bromide and quinine internally for some days before operation. He believes that this course diminishes the hemorrhage during operation and lessens the tendency to chills and fever afterward. Removal of the offending tissue is made with the saw under the bone, the line of section being from below upward and inward. For after-plugging, he prefers absorbent cotton to iodoform gauze.

The Surgery of the Superior Cervical Sympathetic Ganglion.—G. F. Suker finds that in the resection of one or both of these ganglia for glaucoma, simple optic atrophy, Basedow's disease, and perhaps epilepsy, we have a definite surgical intervention yielding positive results, so far as we now know, in selected cases in which heretofore we were at a loss what to do in like cases.

The Determination of Sex at Will.—According to J. G. Davis, the "great law of vibrations" is the only thing which will throw any light on this subject. When male issue is desired, sexual congress should not take place until ten days after the cessation of menstruation. Congress within two days after the cessation or within three days of an expected menstruation will result in female issue.

Studies on Internal Antisepsis.—E. Klebs narrates the results of his experiments on rabbits with inoculation of staphylococcus and nosophen. He considers that this remedy and antinosin (considered in the first instalment of the paper) of great importance in septic infections caused by streptococci and staphylococci.

An Operation for Divergent Strabismus.—D. Webster describes an operation consisting in division of the tendon of the externus and advancement of that of the internus, which gave extremely satisfactory results in a case of divergent squint.

The Treatment of Iritis by the General Practitioner.—N. B. Jenkins advises hot foot baths, salts, and small doses of calomel. The local treatment consists in atropine, darkness, hot applications, and puncture of the cornea.

Albuminate of Mercury (Sapodermin) in the Treatment of Parasitic and Fungoid Diseases.—G. J. Bucknall commends the use of this agent in scabies and reports some cases in which it was employed.

Medical News, February 24, 1900.

Experimental Researches on the Effects of Increased Barometric Pressure and of Foreign Bodies in the Pharynx, Œsophagus, Trachea, and Larynx.—George W. Crile still further confirms the results of other experimenters that animals under chloroform anæsthesia are decidedly more liable to respiratory failure than animals under ether anæsthesia. There is also greater tendency toward reflex inhibitory phenomena in chloroform anæsthesia. On the other hand, the patient may be more quietly and readily reduced under chloroform than under ether, and the tendency to the secretion of mucus is less. In every case where it is possible, local rather than general anæsthesia should be employed. Cocaine is preferable to eucaine. A foreign body lodging in the trachea and not dislodged during coughing can produce only the effect indirectly produced by the powerful respiratory alterations in the act of coughing. If the tube is completely obstructed symptoms of asphyxia will appear. If the foreign body is in the larynx attacks of cyanosis will be likely to occur.

Some of the European Sanatoria for Consumptives, and the Final Aims of Phthisiotherapy.—W. Freudenthal believes that all patients with incipient phthisis should be occupied in some rational muscular work, such as gardening, snow shovelling, light carpentering, and agricultural work of various kinds. Every sanatorium should be provided with facilities to teach these occupations. All this work should go under the supervision of physicians. Sanatoria for the rich and for the poor should be under one financial management, though not necessarily in the same place. A society should be formed by the people most affected by it, viz., the lodges, in order to send the patients to a milder climate, where they can work constantly in the open air; for example, certain parts of Arizona and New Mexico.

A Clinical Contribution to Thyroid Therapy.—Charles E. Hirsch speaks of an affection designated by Jeulain as thyroid chlorosis, which represents the symptoms of ordinary chlorosis together with those of exophthalmic goitre, in which the administration of iodothyrin produced a remarkably rapid and decided improvement. He also reports the happy effect of this treatment in cases of obesity.

Notes on Plague.—By H. E. Deane. A continued article.

Boston Medical and Surgical Journal, February 22, 1900.

On the Advisability of a More or Less General Exploration of the Abdomen when it Has Been Opened for an Operation.—John Homans says that it has several times happened to him to discover conditions and diseases different from the one for which he had opened the abdomen. Three times he removed gall stones whose presence was unsuspected, and whose removal did more for the patient's recovery than the removal of the tumor for which the abdomen was opened. Therefore he advises general exploration in the course of operations without lengthening the original incision.

A Clinical Study of Heroin.—James R. L. Daly considers that this drug possesses many advantages over morphine as a respiratory sedative. It is not a hypnotic.

A Case of Old Shoulder Dislocation.—Frank E. Peckham describes a case of twenty-two months' duration, upon which he operated successfully.

The Unity of the Acute Psychoses.—By Philip Coombs Knapp. See Medical Record, vol. lvi., p. 137.

Psychology and Heredity.—By Robert MacDougall. A continued article.

Wiener klinische Rundschau, February 4, 1900.

Bacterio-Therapy of Leg Ulcer.—Ivan Honl describes his method of treating ulcers of the leg. It consists in the application of substances extracted from the bacillus pyocyaneus. The bacterial flora of leg ulcers presents no specific characteristic elements. Pathogenic as well as saprophytic micro-organisms are present. As to the patient, he is to lay the affected leg in tepid water from time to time. The protein is applied twice daily, while sterilized absorbent gauze thoroughly saturated with the protein is laid on the ulcer, covered with wadding, and fixed by a bandage. Honl declares that this protein cures leg ulcers without exception and in a shorter time than other methods. He also recommends its simplicity and comfort.

An Hour-Glass Stomach Resulting from the Corrosion of Hydrochloric Acid; Gastro-duodenostomy.—Emil Klein reports this case, giving a diagram of the stomach as well as four others representing dried specimens in the pathologico-anatomical museum of the Vienna University. This condition may be either congenital or acquired. As causes of the acquired may be mentioned scar contractures following round ulcer, carcinoma, syphilis, corrosions. In the present instance the patient, a man, drank fuming hydrochloric acid into which matches had been thrown. Two months later gastro-duodenostomy was performed with the happiest results.

Berliner klinische Wochenschrift, February 5, 1900.

Syphilitic Goitre.—E. Werman records the case of a man aged twenty-four years, who passed through a severe stage of specific infection lasting over several years, during which time he was regularly treated. Tertiary symptoms developed as evidenced by cerebral pressure, irritability, loss of palate, etc., and finally an enlargement of the thyroid body. This enlargement diminished under treatment, but recurred upon its cessation. The author calls attention to the fact that enlargement of the thyroid has also been observed after influenza and measles, and he notes the danger of initial changes in the early stages of syphilis, which may be so slight as to escape notice, but which may lay the foundation for serious trouble later.

The Mechanical Distribution of Bony Growths.—H. Maass points out the effects which such conditions may produce in the development of the bony skeleton, especially when the growths occur before the final union of epiphysis and diaphysis.

Cerebral Pressure Symptoms in Typhus Fever.—H. Salamon reports five cases in which the pressure symptoms were due, he thought, to an intra-meningeal exudate excited by the toxins of the disease.

Epidemiology and Prophylaxis of Malaria from the Most Recent Etiological Standpoint.—By A. Celli. A continued article.

Chronic Villous Polyarthritis and Arthritis Deformans.—By Max Schueller. A continued article.

Vratch, January 15 and 22, 1900.

Corporal Punishment in Russia on the Eve of the Twentieth Century.—D. N. Zhbankoff reviews the various opinions expressed by physicians and others regarding whipping as a punishment for crime, and argues forcibly against its continuance. He says it was the hope of many that the new century would see no more of this barbarous punishment in Russia, but we are already on the eve of the twentieth century and there is no sign of its abolishment. He cites with astonishment and reprobation a statement in an English journal that the New York Medico-Legal Society had advocated public whipping as a punishment for certain crimes, but says that the existence of such views in a country where lynch law prevails is quite comprehensible. All physicians, he argues, should protest energetically against the continuance in Russia of what he calls this epidemic of legalized traumatic lesions which exerts so malign a psychical influence over the entire nation.

Post-Partum Sloughing of the Uterus.—Under this title V. G. Bekman describes puerperal gangrene of the uterus. The disease may vary in extent from a small area of the uterine wall to the entire organ, and perforation may or may not occur The affection is much more frequent, the author believes, than is usually supposed, constituting a very appreciable proportion of puerperal affections of the uterus, but it is thought to be rare because many cases pass undiagnosed. This is owing partly to the want of a lucid description of the disease in the text-books—a want which the writer meets in his article. He reports twelve cases occurring in his own practice, five of which have never before been published.

Treatment of St. Vitus' Dance with Large Doses of Arsenic.—V. E. Chernoff reports several cases of chorea in children from eight to twelve years of age, in which he employed arsenious acid in the average daily dose of one-third of a grain, which is larger than that usually allowed for adults. The results of this treatment were excellent, but the author calls attention to its obvious dangers, and says a child taking such large quantities of arsenic should be seen by the physician at least twice a day. The treatment is therefore more feasible in hospital than in private practice.

Bathing of the New-Born.—G. O. Kovarski reviews the arguments for and against the bathing of new-born infants, and concludes that there are no convincing arguments or scientific facts in proof of any injurious effects of baths upon children in the first days of life, and consequently that this old custom may profitably be continued.

Epidemic of Plague in the Village of Kolabovka, Astrakhan Government.—M. I. Arnstamoff gives the histories of the twenty-four cases of plague which occurred at this place in the summer of 1899, the epidemic of which was also described by Levin in the issue of December 4, 1899, of this same journal. See MEDICAL RECORD, vol. lvii., p. 29.

The Bitter Lakes of Batalpashinski.—V. A. Popoff describes two lakes in the Kuban district of the Caucasus, the waters of which contain a large proportion of magnesium sulphate, iron, and aluminium.

The Value of Widal's Serum Diagnosis of Typhoid Fever.—By Th. A. Dombrovski. A continued article.

Progressive Spinal Paralysis.—By L. R. Krever. A continued article.

La Riforma Medica, January 29 and February 6, 1900.

The Resistence of the Red Corpuscles in Some Diseases of the Skin.—Francesco Cenci, from numerous experiments, found that the blood of patients suffering from purpura hemorrhagica was no more resistant than normal blood. There was an increase in leucocytes. Under the action of $FeCy_6K_4$ the red cells are less changed than those of normal blood. The blood of a syphilitic patient treated with NaCl and $FeCy_6K_4$ behaved exactly like normal blood. Treated with pepsin it became darker than normal blood, and the cells changed more quickly. Pancreatin caused no different changes in healthy and abnormal blood. Lactic acid gave the same results in both. The serum of horse's blood (tuberculized) retarded the solvent effects of solution of pepsin, pancreatin, and lactic acid.

Rudimentary Anomalous and Complicated Forms of Mitral Stenosis.—G. Rummo describes cases of pure congenital or fœtal mitral stenosis, of extrafœtal or rheumatic stenosis of a truly inflammatory nature, and of stenosis combined with insufficiency, and gives directions for their diagnosis.

French Journals.

Experimental Tuberculous Meningitis.—A. Sicard concludes that it is possible to produce disseminated tuberculous meningitis either through the blood or by inoculating the cephalo-rachidian fluid directly. The lymphatic system plays no rôle. In the majority of instances there is a diffuse process, but a meningitis *en plaques* may at times occur. The toxins of the bacillus play an important part in the process. The cerebro-spinal fluid is an essential factor in the dissemination of bacilli and their toxins. Exudations and granulations situated in the region of the pia mater are not the result of a polymicrobic infection, but the Koch bacillus or its toxins are alone capable of creating these granulations.—*La Presse Médicale*, February 7, 1900.

Acute Traumatic Arthrites of the Knee in Children.—A. Broca, basing his remarks on a case described, concludes that treatment by arthrotomy is superior to resection of suppurating arthritides of the knee in children, whatever their origin may be. The anterior incision sometimes recommended along the border of the patella should not be practised, but a long incision should be made on either side at the posterior part of the lateral surfaces of the knee, with a large transverse drain under the knee cap. He rarely has occasion to employ lavage.—*La Presse Médicale*, February 7, 1900.

Alimentation in Typhoid Fever.—H. Vaquez considers whether typhoid patients are properly and sufficiently fed by present methods; whether there is danger in giving more food and in a different manner: and what would be the advantages of other methods. The gravity has been diminished by balneotherapy, and the writer believes that to the Brand method can be wisely added that of superalimentation by giving in addition to milk the yellow of eggs, somatose, farinaceous soups, etc.—*La Presse Médicale*, February 10, 1900.

Localization, Elimination, and Origin of Arsenic in Animals.—A. Gautier has shown that certain organs normally contain arsenic. He now studies the origin in alimentary sources and finds minute traces of arsenic in various substances. He also finds that perfect health is incompatible with complete disappearance of arsenic from the system, and points out the medico-legal aspects of detection of minute traces of arsenic in the secretions and organs. (See MEDICAL RECORD, vol. lvii., p. 29.)—*Le Bulletin Médical*, February 7, 1900.

Cancer of the Large Intestine.—H. Lardennois studies the question in all its bearings. Out of two hundred and fifty-five observations collected of total ablation, the mortality was 32.9 per cent. In thirty-two cancers of the colon observed by Brahman the radical operation was performed fourteen times. Six patients succumbed and eight were cured. When the radical operation is possible, it should be attempted. In complications a palliative operation (entero-anastomosis, exclusion, artificial anus) may be done.—*Gazette des Hôpitaux*, February 10, 1900.

Appendicular Colic.—Ch. Talamon studies the prognostic value of colic in the region of the appendix—seven observations. Two lessons are drawn: First, at the onset of colic a purgative should never be given, as one is too much tempted to do; second, the patient should be immediately and strictly immobilized until all pain in the iliac fossa has completely ceased for several days.—*La Médecine Moderne*, February 10, 1900.

Two Cases of Nerve Elongation.—R. de Bovis gives two observations. In one of Raynaud's disease, or local syncope of the extremities, nerve elongation resulted in disappearance of the trophic troubles, but with persistence of a certain degree of paræsthesia. The second case was one of gangrene of the foot due to syphilis and arteriosclerosis. The tibial nerves were elongated with negative result.—*Gazette des Hôpitaux*, February 8, 1900.

Pylorectomy by Billroth's Method.—Guillot, in an article to be continued, finds that pylorectomy by the Billroth operation is preferable to that of Kocher, which in some instances is more difficult, increases the chances of infection, and prolongs unnecessarily the intervention.—*Gazette des Hôpitaux*, February 13, 1900.

The Remote Results of Brushing in the Treatment of Granular Ophthalmia.—Felix Lagrange reviews the technique, and out of one hundred and twelve eyes treated finds seventy-eight per cent. of cures, 4.5 per cent. of improvements, and 17.5 per cent. of failures.—*Le Bulletin Médical*, February 7, 1900.

Treatment of Exophthalmic Goitre by Stabile Voltaization.—L. R. Regnier gives five observations in which good results were obtained, and thinks electric treatment should be tried before surgical procedures. —*Le Progrès Médical*, February 10, 1900.

Archives of Otology, Vol. xxviii., Nos. 5 and 6, 1899.

A Case of Influenza followed by Mastoid Abscess, Sinus Thrombosis, Meningitis, and Death; Autopsy.—F. Allport gives the history of a man aged seventy-six years, who contracted influenza in January, 1899. The attack was severe and accompanied with delirium. During the attack he had abscess of the left ear followed by a swollen and painful mastoid for several weeks. The ear was simply syringed by the attendant. The patient was first seen by Dr. Allport six months later. Soreness of the mastoid on pressure was found, with fistula of the lower posterior bony meatus emitting copious foul pus. The membrana tympani was intact. The operation was done in the usual manner. The bony covering of the lateral sinus was necrosed and the sinus exposed, but was apparently healthy. Recovery from the operation was good, but on the fifteenth day symptoms of meningitis developed, and death resulted fourteen days later. Cerebral abscess had been suspected, and the patient was trephined, but no pus cavity was found. The dura was completely adherent to the skull by old adhesions. There was also a slight puriform thrombus in the left lateral sinus. The author observes that a subnormal temperature as shown in this case does not always indicate a cerebral abscess (none was found on autopsy), and may exist with an acute intense meningitis.

Tinnitus Aurium.—R. Panse concludes a careful study of this phenomenon as follows: Almost all sounds should be designated by their pitch. The pure conduction sounds arise from the diminished outlet of sound, due to rigidity of the conducting apparatus. Inasmuch as the motility of the latter is required for hearing only low notes, its fixation is an obstacle to the outlet of these notes alone. Pure conduction sounds are mainly placed between sixteen and two hundred and fifty-six vibrations. The higher pitched sounds are due to processes in the inner ear. They may be produced (*a*) by reflex from the external meatus, middle ear, and many different parts of the body; (*b*) by changes in the inner ear or the nerve itself. In rare cases, however, low sounds may, perhaps, also originate in the inner ear. Hearing of complex sounds, like melodies, etc., is not prima-facie proof of a cerebral affection. In respect to treatment he gives the rule not to perform any grave operations upon the conducting apparatus when the sounds heard are high pitched, and especially not to attempt removal of the stapes.

On the Thyroid Treatment of Chronic Deafness. —A. Bruck collates the experience of the profession along this therapeutic line, but has not personally seen a single case of positive improvement in the hearing. The translator of the original article, J. A. Spalding, adds that, from his limited experience with thyroid, he should be inclined to recommend it in the early stages of those cases which are likely to result in the so-called chronic catarrh of the middle ear.

Occidental Medical Times, February, 1900.

Leucopathia Unguium.—W. A. Briggs gives the details of a case to which he assigns a neuropathic origin. He also describes a disease of the nails attributed to a mycotic source, and presenting a separation of the distal part of the nail from its bed.

The New Materia Medica and Modern Doctors. —H. D. Powers condemns the multiplication of new and useless remedies, and thinks that students should be taught more thoroughly about the old and reliable ones.

Report of a Case of Sub-Glottic Tumor.—G. H. Powers reports a case of epithelioma. Tracheotomy was done, but the growth extended below the bottom of the tube, and the patient died during the operation.

Report of a Case of General Tuberculosis. Dextro-Cardia, Meningitis; Lumbar Puncture.—S. J. Hunkin reports a case of this nature in a child aged six years. A fatal result followed the operation.

Large Solitary Tubercle of the Heart.—A. W. Hoisholt describes the case of an asylum patient whose heart showed on autopsy a tuberculous growth from the lining of the left ventricle.

Hydrocephalus; Cranial Paracentesis; Lumbar Puncture.—W. N. Sullivan reports a successful case of this description.

Illinois Medical Journal, February, 1900.

The Treatment of Goitre.—A. I. Bouffleur commends the internal use of iodine or thyroid extract or the intra-parenchymatous injection of iodoform or carbolic acid. These failing, enucleation or partial thyroidectomy is indicated. Cysts should be evacuated and injected with iodoform emulsion, this failing, enucleation should be done.

Fatal Perforation of a Uterus Partially Atrophied Post Partum; a Medico-Legal Case.—C. S. Bacon and M. Herzog record the case, and give a *résumé* of the legal points brought out on the trial of the physician who curetted the uterus twelve hours before the patient's death. The physician was acquitted.

The Prevalence of Alcoholism and its Influence on Mortality.—G. W. Webster discusses the points of heredity, inebriate heredity in crime, suicide, insanity, special senses, healing of wounds, sunstroke, tuberculosis, and heart affections.

Nervous Complications and Medico-Legal Relations of Alcoholic Insanity.—D. E. Brower considers some of the nervous diseases set up by alcoholic excess, and considers that the jurisprudence of inebriety needs to be rewritten.

A Sociological View of Criminal Abortion.—W. J. Fernald studies this question from the standpoint of modern sociology, believing that many of the ills of modern society follow from making marriage a civil contract instead of a religious vow.

Traumatic Rupture of the Urethra.—E. J. Senn gives a general description of the condition, and records the clinical history of a case.

Abstract on Pulmonary Tuberculosis.—T. H. Stettler commends the employment of large doses of carbonate of guaiacol.

General Uveitis.—Description of a case by J. W. Smith, with some observations on the subject in general.

Operative Treatment of Exophthalmic Goitre.—A historical and statistical study by Karl Doepfoner.

The Laryngoscope, January and February, 1900.

Appropriate Treatment of Certain Varieties of Nasal Deflections and Redundancy.—D. Braden Kyle considers the following classification of septal deformities: split septum with bilateral bulging, dislocation of the columnar cartilage, simple deflection with thinning, letter-S deflection, deflection with involvement of the bony septum, split cartilage with unilateral bulging, and finally deflection with redundancy of tissue overlapping the septum and extending close to the nasal floor. Deflections may be congenital, from disease, and from trauma. The condition does not always demand surgical intervention. Most of the surgical methods are but modifications of the original Adams operation. Details are given of the various devices which in Kyle's experience have given most satisfaction in the different forms of deviation. He strongly advocates the employment for retention apparatus of malleable tubes which can be moulded to fit each individual case. He has followed the plans advocated in thirty-seven cases, and has had failures in six. For post-operative irrigation he prefers a weak solution of boric acid in sterilized water. Cases must be carefully watched, and the calibre of the tube altered if necessary to prevent undue pressure.

The Principles of Stuttering; Therapeutics.—R. Coen advocates the methodical continuance of breathing-exercises, enumerating, as the principal ones, deep continued inspiration, short expiratory movement of the breath, gradual prolonged expiration, and the holding of the breath. In addition the vocal and speech-producing organs must be regulated. All disturbances which lead to altered innervation must be controlled, the will-power of the patient strengthened, and the general system toned up.

Papillomatous Growth of the Tonsil.—Payson Clark reports the case of a boy aged eight years in whom an irregular mammillated mass occupied the site of the right tonsil. Removal was effected with the cold snare without any special bleeding. Examination of the growth showed that the central part was composed of more or less dense connective tissue with vessels, etc. The peripheral lobulated parts were made up of lymphadenoid tissue and of cellular connective tissue covered with mucosa.

The Therapeutic Gazette, February, 1900.

Some Points of Interest in Connection with Chronic Urethritis.—Orville Horwitz says chronic gonorrhœa is a very grave disease. Besides the long list of dangers to the subject himself there are those to the wife. In follicular urethritis the best results are obtained by steel bougies anointed with Finger's ointment and left *in situ* for five minutes. Congested patches are best treated by protargol, one per cent. gradually increased to two. Granular patches should be treated with solutions of iodine, silver, or copper through an endoscope. Erosions and ulcerations should be treated in much the same way. In prostatic irritability the Winternitz psychrophore often gives good results. When local remedies have been long employed without benefit, they should be discontinued and constitutional treatment given.

Santonin in the Treatment of Epilepsy.—G. Frank Lydston believes santonin quite as efficient, as a palliative, as the bromides, and it may be proven to be quite as curative. He has employed the drug for nearly twenty years and has seen no mention of it in literature. He finds that santonin has a large field of usefulness in convulsive affections of infancy. It is found to act well in cases of epileptics who do not do well under the bromides. It is free from injurious effects. In the adult gr. ii.-v. is the initial dose, and this is increased up to the point of tolerance. Some patients take gr. xx. three times daily for weeks. Characteristic twitchings about the mouth do not occur in the adult. Idiosyncrasies must be looked out for.

The Therapy of Femoral Hernia in the Adult.—T. H. Manley divides treatment into prophylactic, palliative, and radical. An illustrated case is presented and the therapy of femoral strangulation is given, together with the relative mortality and a long table of cases from journal reports. There were 166 cases with 59 deaths (thirty-five per cent.), 150 females with 52 deaths (thirty-four per cent.), 16 males with 7 deaths (forty-three per cent.). In 89 cases of umbilical hernia there were 27 deaths (thirty per cent.); in 83 females, 26 deaths (thirty-one per cent.); and in 6 males, 1 death (sixteen per cent.). A bibliography is added.

A New Surgical Dressing.—T. A. Dewar calls attention to chloretone as a dressing possessing remarkable properties. It is antiseptic, a local anæsthetic, and harmless. In aqueous solution it can be used to prepare wounds, burns, etc., for subsequent treatment. Crystals may be sprinkled over an open surface and chloretone gauze used as a dressing. The writer has amputated fingers on three occasions under the effect of the drug as a local anæsthetic. In operations upon the urethra or the passage of sounds it may also be used.

The Relation between Posterior Urethritis and Prostatic Abscess, and the Treatment of Each.—Ramon Guitéras says prostatic abscess is usually an extension of urethritis along the prostatic ducts. Abscesses usually open into the urethra or the rectum, but at times through the perineum, in the inguinal region, or the ischio-rectal fossa. When surface redness shows, the swelling should be poulticed and opened. The importance of hot rectal douching in the active stages is emphasized, and of combining douches with rectal massage in the later stages.

Treatment of Appendicitis and its Great Mortality.—Mordecai Price believes that a more uniform system of surgical treatment should be adopted in appendicitis. It is rare that there is more than one best way. United experience should point out this way. Mistakes should be more fully reported. Statistics of four hospitals are quoted to corroborate his views regarding the high mortality, and to show that they are not exaggerated. Catarrhal appendicitis he finds four times as prevalent as the genuine appendicitis which it simulates.

Pediatrics, February 15, 1900.

Blood Diseases in Children.—J. M. Taylor gives clinical contributions upon purpura, scurvy, Hodgkin's disease, and arthritis deformans. In a fatal case of hemorrhagic purpura in a girl aged thirteen years, with good history, and nothing to be found in the internal organs, there were hemorrhages from the mucous membranes after spots and ecchymoses had appeared on the skin. There was pain in the head. Coma ensued, followed by death. Calcium chloride, hydrastinine hydrochlorate, ergot, turpentine, and many blood reconstructives were used in vain. In a case of scurvy resembling syphilitic hemiplegia there were complete paralysis of the right arm and leg, and great œdema and severe pain on manipulation. Syphilis was suspected from a flat eruption on the buttocks and a longitudinal ulcer on the raphe of the perineum. Under iodide of potassium recovery took place. A case of Hodgkin's disease in a boy aged seven years was first thought to be one of glandular fever. This, as well as the preceding cases, was very imperfectly studied. Arthritis deformans in a boy aged nine years, seen in Weir Mitchell's clinic, is reported, and the pathogenesis, after Riesman, is reviewed. For a year there were progressive swelling of the joints and diminished power of locomotion. There was no evidence of rickets. Anti-rheumatic remedies made no impression. The case passed from observation.

Fractures.—T. Halsted Myers reports fracture of the neck of the femur in an infant aged six and a half months, with photograph. The tumor suggested separation of the epiphysis or neoplasm. An x-ray picture shows a case of fracture of the tibia and fibula simulating anterior curvature of syphilitic origin, in a child aged eighteen months.

Imperfect Development of the Right Pectoralis Major and Right Scapula.—H. L. Taylor gives with illustrations a case of one-sided flat chest in a girl aged six years. The right scapula was smaller than the left.

Report on the Cause and Prevention of Infantile Mortality.—By Ernest Wende. A continued article.

St. Louis Courier of Medicine, January, 1900.

Sanatoria for Consumptives.—Beverley Robinson believes that for the cure of consumption and prevention of contagion, laws regulating personal and house hygiene would be more effective than the isolation of a few patients in sanatoria.

Results of Eighteen Tests Made for Rendering the Hands Aseptic before Operation.—N. B. Carson has had great success with Weir's method, by which Labarraque's solution is developed by sodium carbonate and calcium chloride in the presence of water.

The Relative Value of Antisepsis and of Improvement in Technique as Regards the Actual Results in Operative Gynæcology. By L. Gustave Richelot. See MEDICAL RECORD, vol. lvi., p. 420.

Torpor of the Retina due to Exposure in the Klondike.—J. Ellis Jennings describes a case of partial snow-blindness, cured by strychnine sulphate, gr. $\frac{1}{50}$ t.i.d., dark glasses, and instillations of atropine.

Typhoid Fever Complicated with Chorea and Diabetes Insipidus.—Carl Orth reports a case of this unusual complication of troubles. The patient made a good recovery.

Functional Derangements of Ocular Muscles.—Edward R. Wright discusses eye strain and its treatment by muscle training, prism wearing, and operation.

Removal of One Hundred and Seven Polypi at One Sitting.—H. W. Loeb accomplished this feat with an electro-cautery snare of his devising.

International Medical Magazine, February, 1900.

The Symptomatology, Complications, and Sequels of Gastric Ulcer.—Boardman Reed says that the three most prominent symptoms of gastric ulcer are pain, hemorrhage, and circumscribed tender spots. Vomiting after taking food is another rather frequent symptom. It is very exceptional in cases of ulcer to find the stomach contents deficient in hydrochloric acid. The appetite is generally good—often excessive. The complexion varies. According to Welch the largest proportion of cases occurs between the ages of twenty and thirty years. Nearly two-thirds of the cases are of women. A tumor can sometimes be felt. The most important complications are: (1) rapid and possibly fatal collapse; (2) partial perforation with patches of local plastic peritonitis; (3) perforation with escape of gastric contents into the peritoneal cavity and resulting peritonitis; (4) subphrenic abscess. The sequels may be a contraction or closure of the cardiac or pyloric orifice; prostration, anæmia, and cachexia, or gastric ulcer may be followed by cancer.

The Diagnosis of Some Ocular Maladies by the General Practitioner.—J. A. Patterson quotes Risley on the location of pain in ocular maladies: "In optic nerve diseases, there is in many cases pain in the front of the head, on top, but it is not a vertex pain. The pain, when associated with eye affections, occurs in the brow, occiput, back of the eyes, and in the temples, in point of frequency in the order named. Simple eye strain, particularly in children, will usually give rise to brow pain. If associated with some abnormality of the ocular balance, there will usually be occipital pain also." The diagnosis of muscular disabilities is as intricate as it is important, and requires very careful testing for the perception of all the minute features. In making pupillary examinations the physician should notice whether the pupil reacts to light stimulus promptly, sluggishly, or not at all. The ophthalmoscope is an invaluable adjunct in the diagnosis of ocular maladies.

Stricture of the Urethra.—J. D. Thomas favors the following method of treatment in this affection: After passing the filiform, pass over this as a guide a small tunnelled divulsor, and, opening this up, divulse to about No. 20 F. After the removal of the divulsor and filiform, a No. 20 F. metallic sound is passed, which enables the patient to urinate freely; the bladder is relieved, and the patient is in good condition for treatment by gradual dilatation.

The Importance of the Early Recognition and Treatment of Gonorrhœa in the Female.—Edward E. Montgomery declares that syphilis is not nearly so baneful in its influence upon the future health of the woman as gonorrhœa. For when the latter affection has once invaded the deeper structures of the genital tract, it is beyond the physician's control and produces changes in structure and relation which can be relieved only by a sacrificial operation.

Importance of Thorough Urinary Examinations. The Needed Preparations, Apparatus, etc.—A. Robin believes that uranalysis is often incomplete. Apparatus should be cleaned as soon as the work is finished. Printed blanks are valuable. A most useful preservative is formalin.

Some Practical Points in Infant Feeding.—Howard S. Kinne emphasizes the importance of regular feeding: the child should remain at the breast for fifteen to twenty minutes, but not longer. Night nursing should be avoided.

Franklinic Electricity and Methods of Application.—By Margaret A. Cleaves. A continued article.

The Century of Surgery.—By W. Wayne Babcock.

Deutsche Aerzte-Zeitung, February 1, 1900.

Treatment of Erysipelas with Antibactericidal Remedies.—Max Heim mentions a variety of drugs—iodoform, alcohol, carbolic acid, turpentine, etc.—which have been used with more or less favorable results. The antistreptococic serum (Marmorek) is useless. In migrating cases, the application of equal parts of ichthyol and vaseline, together with Riedel's method of multiple scarification and washing with bichloride solution (1 : 1,000), often brings the disease to a close. Four successful instances are recorded.

Present Status of Treatment of Hypertrophic Rhinitis.—L. Réthi concludes that in large diffuse hypertrophies energetic treatment with trichloracetic or chromic acid, nitrate of silver, or galvano-cautery is indicated. In polypoid hypertrophies the galvano-cautery, snare, or cutting is indicated. The methods applied are carefully described. Hypertrophies of the septum are best removed with the snare.

Observations on the Use of Heroin.—Jacob Wilsner used the muriate internally and subcutaneously, four hundred and eighty-one times in sixty-five cases, irrespective of age and sex. Only narcotic, analgesic, and sedative effects were tried, with the result that it bids fair to replace morphine and codeine for these purposes. Smaller doses are necessary and the after-effects are less than with morphine.

Observations upon the General Deficiency of Albumen in Nourishment.—Ludwig Hellwig takes issue with Finkler, who says that most people do not take sufficient albumen with their food. Quotations from Finkler and Pflüger are freely discussed.

Giornale Medico del Regio Esercito, December 31, 1899.

The Mosquito-Malaria Theory.—Claudio Sforza takes up the question of the prevention of malaria among soldiers, and, basing his remarks on the theory of the connection between the disease and certain varieties of mosquito, urges that greater care be exercised in the selection of localities for the encampment and drilling of soldiers. The latter are exposed both day and night to the punctures of these insects. He also recommends the wearing of the hoods and gloves recommended by Professor Celli for railway employees, the use of mosquito netting when practicable, and of various substances supposed to be obnoxious to mosquitos.

Aneurism of the Innominate Artery.—Luigi Rugai reports and describes a case. The tumor is of small size, and the pressure symptoms are very slight. Rest, careful dieting, and potassium iodide will be the treatment given, unless more alarming symptoms should call for ligature of the carotid and subclavian arteries.

Archives Générales de Médecine, February, 1900.

The Self-Help of the Organism in Certain Cases of Angina Pectoris.—Joseph Pauniski studies the various compensatory influences in cases of heart disease causing stenocardia, and concludes that hypertrophy is the chief one. Improvement in the general nutrition of the patient favors this hypertrophy, but this does not mean superabundant nutrition which might overtax the myocardium. The greater the amount of hæmoglobin in the blood, the slower is the circulation and the longer the diastole, an essential condition to nutrition of the heart, since it fills only during diastole. Hæmoglobin may be obtained by increasing the albuminates or by diminishing the water in the organism.

Clinical Study of the Contraindications to the High-Altitude Treatment.—L. Murat considers cachexia a contraindication in most cases; laryngeal phthisis is usually aggravated by mountain air; emphysema, erethism, acute phthisis, or acute attacks in the course of chronic phthisis are all contraindications. Hæmoptysis, on the other hand, is usually benefited by high altitude. Kidney disease, rheumatism, and white swelling are rendered more painful, and phthisical patients suffering from these complications should not be sent to an altitude as great as forty-six hundred feet.

Ganglional Tuberculous Cavity Opening into the Aorta, Left Bronchus, and Œsophagus.—L. Brodier and P. Lecène describe this condition in a patient who was not suffering from pulmonary tuberculosis.

Botryomycosis Occurring in Man.—By Antonin Poncet and Louis Dor. A continued article.

Various Forms of Purpura and Visceral Affections.—By C. Oddo and Olmer. A continued article.

Il Policlinico, January 15, 1900.

The Consequences of the Escape of Urine into the Peritoneum.—L. Rizzo, as a result of experimentation on animals, concludes that small amounts of urine in the peritoneum have neither local nor general action; doses up to one-thirteenth of the animal's weight have no local action, but cause a grave uræmic condition. Higher doses cause death. The presence of urine in the peritoneum renders this serous membrane most vulnerable to the infections. The peritonitis which by organization closes wounds of the intraperitoneal tract of the urinary passages is not due to the action of urine, but to the fact that a bloody surface is in contact with the peritoneum.

Bacteriological Researches in Normal and Diseased Fallopian Tubes.—Guiseppe Bellei found that healthy tubes are not free from germs; that the micro-organism most frequently causing purulent salpingitis was the staphylococcus pyogenes albus, but other germs may also cause the process. He at no time found any association of pathogenic microbes in purulent salpingitis, and only rarely found a pathogenic germ with one or more saprophytes. In chronic salpingitis he found no micro-organisms. The saprophytes found in the tubes are either special to this organ, or have assumed special characteristics due to their environment.

The Genesis of Lipoma.—Eriberto Aievoli gives a number of reasons for believing that in the future lipomata will not be included with neoplasms, in the strict meaning of the term, but will be considered as belonging to the class of trophic lesions. As to the reasons for the disturbance of equilibrium in the physiological deposition and removal of fat, the author holds that in the distribution and function of elastic tissues, or their influence upon the distribution of nutritive fluids, will be found the solution of the problem.

Fibrous and Muscular Abnormalities of the Fascia Transversalis.—Guglielmo Romiti describes some peculiar conditions found in the course of autopsies, and upon living subjects.

Deviations and Contractures of the Spinal Column of Neurotic Origin, Especially Hysterical Scoliosis.—Erasmo de Paoli describes several cases of this affection.

Reviews and Notices.

State Board of Massachusetts, Thirtieth Annual Report, 1899. 8vo, pp. 878.

This rather bulky volume contains, among other useful documents on the public health of Massachusetts, an excellent and exhaustive report on the water supply and sewerage of towns.

Lea's Series of Pocket Text-Books. Diseases of Children: A Manual for Students and Practitioners. By George M. Tuttle, M.D. Edited by Bern. B. Galaudet, M.D.

This new manual has just appeared. It describes a series of infants' disorders, and gives the management of the same without going into extensive details. It is well adapted for the purpose of the author. We take exception to the otherwise good monochrome—but ask the author to credit the same to Dr. Flindt, New York Medical Record, October 21, 1899. The book is well written, and has some very good illustrations.

Transactions of the Medical Society of the State of North Carolina. Forty-sixth annual meeting, held at Asheville, N. C.

After the address of the president and the annual oration, this volume is divided into the various branches of practice of medicine, obstetrics, pathology and microscopy, medical jurisprudence, anatomy and surgery, materia medica, and therapeutics. A code of medical ethics, covering fifteen pages, proves a source of great instruction.

The Transactions of the Medical Society of the State of California. Twenty-ninth annual session, Monterey, April, 1899.

Unlike the reports of most society meetings, this volume offers numerous interesting and instructive articles as its main contents, giving only secondary importance to constitution and by-laws, committee reports, member lists, etc.

Transactions of the Vermont State Medical Society, 1898.

This little volume contains the transactions of the eighty-fifth annual meeting held at Brattleboro. It presents a number of interesting papers, with their general discussion, a list of members and past presidents, and the by-laws and constitution.

Mt. Sinai Hospital Reports. Volume I., for 1898. Edited for the Medical Board by Paul F. Mundé, M.D., LL.D.

The hospital and editor are to be congratulated upon the very excellent and practical manner in which this maiden report has been presented. Each department has contributed its share, in a way which carries conviction and instruction with it, so that in all the volume proves a very valuable source of information.

Transactions of the Medical Society of the State of West Virginia. Held at Weston, May 17, 18, and 19, 1899.

This volume, though covering but a hundred pages, contains reading-matter whose value is in inverse proportion to its quantity. The article on the "Present Status of Appendicitis," by Hupp, would repay careful study, as it is clearly and thoroughly presented. The Transactions have many other short and instructive contributions.

The Retrospect of Medicine. A half-yearly journal. Edited by James Braithwaite, M.D., and E. F. Trevelyan, M.D. Vol. 119. July, 1899. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited.

It is largely a matter of choice with medical readers whether they require or desire their scientific pabulum served up weekly, bi-weekly, monthly, quarterly, half-yearly, or in an out-and-out year book. The market supplies medical literature of current nature in all these and many other forms. Recent reviews of the publication before us appearing in journals interested in the success of other and newer ventures would make it appear that "Braithwaite" has outlived its usefulness. It is the same half-yearly journal it was half a century ago, giving abstracts and short articles from medical journals, and showing the most important indications of treatment, published by different writers during the half-year, arranged alphabetically under general headings of practical medicine, surgery, obstetrics, and gynæcology, these being subdivided to cover the field. The "Retrospect" has always been a welcome visitor to the Medical Record's table, and is still; and we could advise no old or recent subscriber to give it up in an attempt to get better food more promptly served for the same outlay.

Practice of Medicine: A Manual for Students and Practitioners. By George E. Malsbary, M.D., Assistant to the Chair of Practice, Medical College of Ohio, University of Cincinnati; Assistant to the Lectureship of Clinical Medicine, Good Samaritan Hospital, Cincinnati. Philadelphia and New York: Lea Brothers & Co.

This is one of the series of pocket text-books issued by this publishing house, and edited by Dr. Gallaudet. While it is true that the manual has the advantage over a deep treatise that it can be published quickly and include the latest fashions in medicine, still there is always the possibility that the work has been too hastily done in these smaller works. A soldier is no better than his feet; a chain is no stronger than its weakest link, and a book is no better than its worst page. The work before us has one weak if not worst page. In defining the pox, the author says: "Two or three months later," (after the primary lesion) "the secondary lesions develop." "The third stage of the disease develops after a period of three or more years, with falling of the hair, etc." Under treatment we read: "Some advise excision of the primary sore, since it is a focus of infection. When this is done, medicinal treatment is begun at once; but usually active treatment is deferred until the second stage." We cannot regard the postponement of active treatment for "two or three months" as the best teaching of the day. Differential diagnosis and treatment, which should be the strongest features of such a book, are noticeably weak.

A Text-Book of Materia Medica, Therapeutics, and Pharmacology. By George Frank Butler, Ph.G., M.D., Professor of Materia Medica and Clinical Medicine in the College of Physicians and Surgeons, Medical Department of the University of Illinois, etc. Third edition, thoroughly revised. Philadelphia: W. B. Saunders. 1899.

Nothing has been omitted by the author which, in his judgment, would add to the completeness of the text, and the student or general reader is given the benefit of latest advices bearing upon the value of drugs and remedies considered. What has seemed detail of no great importance has been excluded to make place for weightier matter. In its new form, this volume of eight hundred and seventy-five pages must be regarded as a thoroughly up-to-date aid in instruction in the branches covered. There is at the end a clinical index, making the matter available in a very practical way.

The Logic of Figures; or, Comparative Results of Homœopathic and Other Treatments. Edited by Thomas Lindsley Bradford, M.D. Philadelphia: Boericke & Tafel. 1900.

Drawn from various sources, statistics are here offered by the writer and compiler to show by the "logic of figures" the superiority of his school of teaching and practice. Though not exhaustive the attempt has been made to include all important statistics for the past fifty years covering death rates in the hospitals, asylums, etc., under the different schools. There is a bibliography of statistical books and articles.

Bee-Line Therapia and Repertory. By Stacy Jones, M.D. Second edition. Philadelphia: Boericke & Tafel. 1899.

The author of this little, soft-covered pocket-book of three hundred and thirty-three pages thinks that "if we can get three legs to the stool of affiliation we will have a pretty sure base for a successful prescription." He therefore advises the physician who uses this work to consult especially sections on "Cause," "Aggravation," and "Amelioration." New features of this edition are chapters on "Person" as distinguishing the peculiar physique of the patient; and on the various kinds and uses of suppositories. The title "Bee-Line" has been chosen because of the specific indications for remedies as set forth.

A Practical Treatise on Materia Medica and Therapeutics. By Roberts Bartholow, M.A., M.D., LL.D. Tenth edition, revised and enlarged. New York: D. Appleton and Company. 1899.

To the student of twenty or more years ago who prepared for his examinations from the first edition of "Bartholow," the present volume will indicate the many advances scored in the matter of drug medication. There will also be discovered such changes as increased space, omission of references now deemed unnecessary in order not unduly to increase the number of pages, a brief account of the newest remedies, and a special article on prescription writing. The student or practitioner who now becomes acquainted with this justly popular work for the first time will find within its pages, attractively presented, all that is reasonably required to be known about drugs and their action, in conformity with the only official standard, the United States Pharmacopœia.

Warner's Pocket Medical Dictionary of To-Day, comprising Pronunciation and Definition of Ten Thousand Essential Words and Terms used in Medicine and Associated Sciences, and Tables of Arteries, Nerves, Muscles, etc. Arranged for convenient reference by William R. Warner. Pp. 374. Philadelphia: William R. Warner & Co. 1898.

This is a most handy little volume of the right size as a pocket companion and especially adapted to medical students who are being introduced to many new terms. Many of the very common words have been omitted. This is the second edition and has been revised to date.

The Medical News Visiting List for 1900. Weekly (dated, for 30 patients); Monthly (undated, for 120 patients per month); Perpetual (undated, for 30 patients weekly per year); and Perpetual (undated, for 60 patients weekly per year). The first three styles contain 32 pages of data and 160 pages of blanks. The 60-patient Perpetual consists of 256 pages of blanks. Each style in one wallet-shaped book, with pocket, pencil, and rubber. Philadelphia and New York: Lea Brothers & Co.

This little book is most admirably arranged, and contains many useful tables and references. The printed contents consist of articles on Urine Analysis, Important Incompatibles, Artificial Respiration, Table of Eruptive Fevers, Poison Antidotes, etc. The blanks are arranged for daily record of visits, general memoranda, obstetric engagements, vaccinations, death register, addresses of patients and nurses, and cash account. It should suit excellently the needs of the general practitioner.

Clinical Lectures on Neurasthenia. By Thomas D. Savill, M.D., Physician to the West End Hospital for Diseases of the Nervous System, London, etc.

The English edition of this well-known book was reviewed in our columns on July 15th last. We are in receipt of an American edition of the work, in every way the equal of the original, just published by arrangement with the author by Messrs. William Wood & Company, New York. (Muslin, $1.50 net.)

Clinical Society's Transactions. Vol. XXXII. London: Longmans, Green, & Co. 1899.

It is with deep interest that one reads the last volume of the Transactions of the London Clinical Society, not only because of the intrinsic worth of the papers read and the clinical value of the cases that were presented, but also because the work of this society illustrates how much can be accomplished for clinical medicine when the proper spirit pervades the members of the association. It is indeed no wonder that the meetings of this society are well attended, for each member strives to present briefly and yet minutely the very best clinical material. To review either the papers that were read or the cases that were presented would hardly be possible in the space that can be devoted to this notice of the society's Transactions, and the volume can only be recommended to the entire rank and file of the profession, as containing most interesting and unique material. The book is excellently printed, the illustrations are particularly good, and the contributors, editors, and publishers are all to be heartily congratulated upon the manner in which their work has been accomplished.

Obstipation. By Thomas C. Martin, Ph.D., M.D., of Cleveland, Ohio. Philadelphia: Medical Publishing Company. 1899.

The author styles the book "a practical monograph on the disorders and diseases of the rectal valve," and devotes the first portion to a critical review of the literature bearing upon the existence of this anatomical structure. He then details his method of rectal examination. This he makes a complicated procedure, and for its perfection he has devised a special table and quite an array of instruments; whereas, with a patient in the knee-chest position, a direct ocular inspection of the interior of the rectum, when it is distended with air, is quite simple and easy. The last half of the book deals with the importance of abnormal conditions of the rectal valve in producing obstipation. In infancy the deficient muscular development of the lower segment of the bowel, and the greater length and mobility of the sigmoid flexure, are certainly far more important factors than the rectal valve in causing obstipation; and in adult life, with the exception of those rare cases of congenital membranous septa which obstruct the lumen of the bowel, it is not the rectal valves which cause the obstipation, but the inflammatory processes and new growths, which affect the bowel at the site of these structures, and it is to the pathological condition that our treatment must be directed, and not to the rectal valve.

Bacteria, Especially as They are Related to the Economy of Nature, to Industrial Processes, and to the Public Health. By George Newman, M.D., F.R.S. Edin., D.P.H. Camb., etc.; Demonstrator of Bacteriology in King's College, London. Illustrated. Pp. 348. New York: G. P. Putnam's Sons. London: John Murray. 1899.

This volume is the sixth in the "Science Series" edited by Prof. J. McKeen Cattell and F. E. Beddard, and is fully as interesting and instructive as its predecessors. The author does not claim to put forward the results of his own original work nor to give a complete technical guide to the laboratory. His purpose has been to deal with the subject in a popular way, and in this attempt he has most happily succeeded. There has been a great need for just such an exposition of the life histories of bacteria, and Dr. Newman has taken pains to describe the advantageous uses as well as the disease-producing activities of our friends the enemy. The book is divided into various chapters on the biology of bacteria—bacteria in water, in air, in the soil, in milk, milk products, and other foods, the relation of bacteria to fermentation, the question of immunity, and antitoxins and their relation to disease. The publishers have produced a well-printed volume, well bound, and of neat appearance, while the illustrations are sufficient and to the point.

The Veil as a Cause of Erythema of the Nose and Cheeks.—O. Rosenbach (*Berliner klin. Wochenschrift*, October 1, 1899) calls attention to the frequency with which women who wear veils in winter suffer from redness of the tip of the nose and the cheeks. This is not due to any draught of cold air; on the contrary, the heavier the veil, the worse the condition. He attributes it (*a*) to the roughness of the threads of the veil, and (*b*) to abstraction of warmth by the veil from those parts of the face with which it comes immediately in contact—"acting like a cataplasm." The blood is thus drawn to these parts, and the capillaries become over-distended. On the cheeks the area of redness is limited to the points of separation of the veil from the skin. The condition is naturally increased upon entering a warm room.

Therapeutic Hints.

Treatment of Simple Appendicitis.—D'Arcy Power (*British Medical Journal*, November 25th) writes as follows regarding this subject: Medical treatment may be adopted so long as the patient seems fairly well, his pulse is regular, firm, and not too rapid; if his respiration is full and painless, his belly is but little distended, and if the stools are normal, or there is only slight constipation. It is better not to use opium in any form, because it hides the tenderness and masks the facial changes, which are the only safe indications of the course which the disease is running. As a routine treatment of a straightforward and simple case of appendicitis I have seen the best results follow the method to which Mr. Maylard has recently drawn renewed attention. It consists in the immediate administration of a copious enema of warm soap and water, followed by teaspoonful doses of magnesium sulphate in two wineglassfuls of warm water given hourly, the dose being repeated six or eight times until the bowels begin to act. A hot boric-acid fomentation or an ice-bag is applied to the right iliac region, the choice being determined by the relief which the patient obtains, though the surgeon prefers the ice-bag. The patient must be kept in bed until the swelling and all the tenderness have left the right iliac region, and he must be fed upon food which is easily digested, that neither constipates nor forms massive stools.

Boric-Acid Poisoning.—Dr. Grumpelt (*Sem. Médicale*, No. 15, 1899) reports a case of severe intoxication following the employment as an enema of about a pint of a one-per-cent. solution of boric acid. The toxic manifestations consisted of erythematous, papular, and bullous lesions on the hands, marked dryness of the skin, high fever, nausea, and headache.

The Therapeutics of Acute Pneumonia.—Dr. Thomas G. Mays (*Merck's Archives*, May, 1899) believes that cold is paramount to everything else in the treatment of acute pneumonia. He applies ice in large, flat rubber bags to the head and chest. This measure reduces the fever, lessens the tendency to convulsions in children, and allays the irritability of the nervous system in adults; it limits and checks the extension of the pneumonia process by contracting the pulmonary capillaries; it promotes resolution, and disperses the products of exudation; it acts as a profound sedative to the circulatory and respiratory centres; it supports the function of the heart; it alleviates the difficulty of breathing; it abates pain in the chest, and it gives general rest and comfort to the patient.

Preventive Treatment of Impending Diabetic Coma.—Upon the appearance of the aceto-acetic acid reaction in the urine place the patient on a strict milk diet. Administer internally 30 gm. sodium sulphate and 20 gm. sodium bicarbonate. Give cardiac stimulants, digitalis, caffeine, etc. To combat the ferment action, give ammonium fluoride gr. $\frac{1}{60}$ in water, after each cup of milk. Inject twice daily 1 gm. of a twenty-five-per-cent. solution of sodium glycero-phosphate, and begin oxygen inhalations.—Robin.

The Medical Treatment of Puerperal Infection.—Dr. Howard W. Longyear (*Medical Times*, December) summarizes the treatment as follows: Local Treatment—Early recognition and destruction of pseudo-membrane by topical applications is of great importance. The iodine, carbolic acid, and chloral mixture is a safe and efficient application for this purpose. The intra-uterine douche, frequently applied, is of most value in the forms of infection unattended by the formation of a pseudo-membrane, but is useful also in connection with local applications. Peroxide of hydrogen per vaginam is useful in all forms of infection. Frequent packing of the vagina, previously dried, with iodoform gauze, is especially useful in cases attended with pseudo-membrane. Inspect infected cases daily with the speculum. Some uncomfortable surprises may thus be avoided, and the local treatment will be most intelligently carried out. General Medication—Quinine in large doses twice daily; whiskey and strychnine to support the heart, if indicated; nuclein and protonuclein in all cases; mercurial and saline cathartics at first in all cases, then as indicated. Serum therapy to be applied in all cases when the Klebs-Loeffler bacillus or the streptococcus can be demonstrated by bacteriological examination, and also in all other cases when such examination has not been made, but in which these specific varieties of infection are probably present. Streptococcus antitoxic serum is to be used persistently to prevent pus formation and symptoms of systemic infection, even if local symptoms and high temperature persist.

Asthmatic Attacks.—Subcutaneous injections of atropine in doses of ½–1 mgm. are followed by prompt relief; the earlier the administration during an attack, the better.—Riegel (*Deutsch. med. Wochenschr.*, 1899, No. 41).

Contraindications to Carbonic-Acid Baths in Circulatory Diseases. — Carbonic-acid baths in general cause increase of blood-pressure; occasionally a diminution is noted. Diminution in the heart's dulness or percussion and increase in urine excreted are observable in some cases. The baths are therefore contraindicated when apoplexy is threatening, or when the heart is just compensating and cannot respond to greater demands.

The Effect of Codeine on Coughs.—In epidemic bronchitis codeine is a valuable remedy for the relief of the harassing pain of the cough, and when combined with one of the coal-tar antipyretics the analgesic effects become more pronounced. It is a favorite drug in the cough of phthisis and chronic bronchitis, and its sedative influence is highly satisfactory, clinical data having shown it to be the best succedaneum for opium. Another advantage of codeine over morphine, one of special value in bronchial catarrh, is that the patients not only cough less but also expectorate more easily than after morphine. The cough-dispelling power of codeine is such as to make it indispensable in phthisical patients, and a point of great importance in these cases is that it does not impair the appetite or digestion, and can therefore be used uninterruptedly for months.—George J. Lochboehler, *Journal of the American Medical Association*, December 2d.

The Nutritive Value of Albumose Peptone.—It is impossible to maintain life upon peptone alone, as it is upon all other strictly nitrogenous foods. Upon the addition of a small amount of carbohydrate, the nitrogenous loss from the body, with the same amount of albuminous food, is very much retarded. Peptone must be regarded as not only able to replace native albumin as a means of checking nitrogenous loss, but also as a means of increasing albuminous tissue. For a period of forty-five consecutive days, at least, peptone causes no diarrhœa or disturbance of the stomach.—A. E. Austin, *Boston Medical and Surgical Journal*, November 30, 1899.

Creamy Thrush.—For this frequent form of stomatitis in infancy to arise the saccharomyces albicans must be introduced from without, and must find a peculiar condition of the digestive tube favoring the growth of this fungus. On this are based the rational treatment and care necessary to prevent its spread. Cure the gastro-entritis which has preceded it. Erythematous stomatitis, which also precedes it, as a rule, may be prevented by good hygiene. Wash the mouth several times daily with Vichy water, or five-per-cent. bicarbonate of sodium solution, or apply:

℞ Borax	5
Glycerin	20

Wash out the stomach also with Vichy water. In rebellious cases antiseptics should be used with care and chiefly by the physician himself. Carbolic solutions are not to be used. Internally a teaspoonful of a half or one per cent of resorcin solution should be given every two hours.

℞ Saccharin	1
Spt. vini rect. (60 per cent.)	50

S. A teaspoonful in a glass of water as a mouth wash five times daily.

—Labbé, *La Presse Méd.*, December 13, 1899.

For Coughs.—

℞ Heroin	gr. $\frac{1}{18}$
Ammon. hypophos	gr. iij.
Hyoscyami	gr. i.
Pin. alb. cort	gr. iiiss.
Bals. tolutan	gr. $\frac{1}{4}$
Glycerini puri	ʒ i.

M. S. For dose.

—*Ex.*

Balsamic Pills.—

℞ Terpin	0.05 cgm.
Sodii benzoat	0.10 "
Picis veg	q.s.

M. For one pill. Make forty. S. Take ten daily.

—Delesquelle.

Psoriasis.—

℞ Acidi salicylici,	
Acidi pyrogallici,	
Ammon. sulph. ichthyol	āā gr. xlvi.
Ol. oliv	ʒ iiss.
Adipis lanæ	℥ iv.

M. S. Apply twice daily.

This produces no irritation nor discoloration of the skin.—Unna.

Local Asphyxia of the Extremities.—In a certain number of cases sulphate of quinine has given incontestable results.

℞ Quin. sulphat.,	
Ergotin	āā 0.05 cgm.
Pulv. digitalis fol	0.005 mgm.
Ext. belladonnæ	0.001 "

M. For one pill. S. Give two to four before each meal.

—Plicque, *La Presse Méd.*, No. 92, 1899.

Phthisis.—

℞ Ichthyol.,	
Aquæ	p. æq.

M. S. One to two drops in tablespoonful of water after meals, gradually increased to ten drops t.i.d.

—Wertheimer.

Phtheirius Pubis.—

℞ Hydrargyri bichloridi	0.25 cgm.
Spt. terebinth	30 gm.
Glycerini	40 "
Spt. lavandulæ	175 "

M. S. Apply.

—*Gaz. des Hôp.*

Treatment of Corns.—Dr. E. L. Wood, of Dansville, N. Y., writes: "A radical cure for corns consists in paring the callosity as closely as possible without causing any hemorrhage; then placing in the centre of the corn a very small drop of croton oil, and bandaging for twelve hours. Then remove the bandage and paint the corn with reliable cantharidal collodion; a pustular bleb will result, in the formation of which the entire callosity, nucleus and all, will be raised without very much pain from the tissues beneath and can be easily removed. The process should be conducted under the care of a surgeon to insure prompt sterilization of the part after the callus is removed. Healing has always been rapid, not requiring more than three or four days, with no liability to recurrence unless the foot is afterward abused. I have treated active, working patients without a loss to them of more than a half day of time."

Hepatic Colic.—Avoid the hypodermic use of morphine by giving:

℞ Ext. bellad.,	
Ext. opii	āā 0.20 cgm.
Ol. theobromatis	q.s.

M. For one suppository—make four such. S. One repeat in half an hour, then every hour.

Apply over the liver region a flax-seed poultice made with laudanum. Give internally:

℞ Sodii bicarbon	4 gm.
Aq. destil	100 "
Syr. simp	30 "

M. S. A teaspoonful every half-hour, alternating with:

℞ Ac. citric	4 gm.
Aq. destil	100 "
Syr. limonis	30 "

A teaspoonful on the quarter hour.

—Bacaloghi.

Tender Feet, especially among soldiers. Harden the epidermis and destroy bacteria with salicylic solutions five per cent.; remove offensive odors with formic-aldehyde solutions two per cent., or apply tannoform powder (formaldehyde added to an aqueous solution of tannin and precipitated with hydrochloric acid).

Sperminum is said to act as a ferment in textural respiration, oxidizing the products of regressive metamorphosis. To it is ascribed the property of preserving the system from auto-intoxication. Its use is indicated when it is necessary to raise the tone; when there is diminished intra-organic oxidation, in anæmia, gout, rheumatism, phthisis, neurasthenia, etc. It seems contraindicated in mania and epilepsy.—"Notes on New Remedies," December, 1899.

Carbolic Acid in Tetanus.—Ten minims of a ten-per-cent. carbolic solution were injected hypodermatically, and after fifteen minutes twenty minims in addition, in a boy of twelve with general symptoms of tetanus, dyspnœa, and opisthotonos ten days after injury to the foot. After the third day there was improvement, and he gradually recovered.—Woods, *New York Medical Journal*, September, 1899.

Honey-Bee Therapy.—The source from which the honey is gathered will influence very greatly its value in medicine.—L. O. Howard.

Most of the honey served to guests in Swiss hotels is said to be merely glucose flavored with honey.

Apis mel has been successfully used in dropsy, possessing decided diuretic and diaphoretic properties.—Miller.

Overworked and feeble individuals are saved work for their digestive machinery by eating honey instead of cane sugar.—Professor Cook.

Creosotal.—Two and a half grams four times daily in emulsion of hot milk are said by Cassoute to be tolerated by adults in acute broncho-pulmonary affections, while children up to one year of age can be given from 0.25 cgm. to 1 gm. daily in four doses; children from four to six years of age can take 3 gm. to 4 gm. daily. The dose given in Coblentz's "Newer Remedies" is ♏ iii.-v.

Society Reports.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 10, 1900.

T. Mitchell Prudden, M.D., President.

A Case of Congenital Renal Malposition with Anomalous Arterial Supply.—Dr. Harlow Brooks presented a specimen taken from a negress, twenty-eight years of age, who had been healthy previously, and had borne one child at full term without any uræmic or other complications. About one year later she had again become pregnant. When supposed to be about three months pregnant she had entered the Harlem Hospital complaining of cramp-like pains in the region of the appendix. She had no fever, and palpation at McBurney's point did not give the characteristic tenderness or sensation to be expected in appendicitis. The urine had not been examined until rather late in the case, and then had been found to contain a small quantity of albumin, and some blood corpuscles. There had been at this time still no elevation of temperature. Pelvic examination by the house surgeon had shown the woman to be pregnant, and had revealed the presence on the right side of a mass supposed at the time to be a cystic ovary or a pyosalpinx. The woman had been rather irritable, but had gradually passed into a comatose condition, when a diagnosis of uræmia had been made. The autopsy had revealed a twin pregnancy at about the third month. One umbilical cord was tied in a hard knot. The uterus was in the normal position. The left kidney had been about the normal size, but exhibited an acute hemorrhagic nephritis. The right kidney had been found below the brim of the true pelvis, and the enlarging uterus had jammed it up against the bones of the pelvis. The tissue of this kidney was extremely anæmic. There were two renal arteries on this side, one given off just above the bifurcation of the abdominal aorta into the common iliacs; the other branch had been derived from the sacra media. The enlarging uterus had compressed and rotated the kidney, cutting off the blood supply from the sacra media, and also from the upper renal artery, which was given off slightly above the sacra media. It was this that had caused the anæmia of the kidney and probable loss of function. This sudden increase of function explained the pain and the rather sudden onset of the acute nephritis on the other side. This position of the kidney in the pelvis was not particularly rare, and it was not extremely rare for the sacra media to become the renal artery, but in all such non-functionating cases found in the literature the kidney had been apparently deprived of its function. In none of these other cases, moreover, had any symptoms been produced. In the case just reported the malposition of the kidney had probably caused death. In her first pregnancy the uterus had risen out of the true pelvis before it had been large enough to compress the kidney; in the last pregnancy, however, twins being present, the uterus had enlarged sufficiently to compress the kidney before it rose from the true pelvic cavity. The only other interesting feature of the case was the general smallness of the arteries of the body.

Dr. Hodenpyl asked if the entire blood supply had been cut off from the kidneys.

Dr. Brooks replied that he thought it had been, for the reason that the pelvic blood-vessels had been pretty well filled, and the renal vessels apparently bloodless. The reason that gangrene had not taken place was that the nipping of the kidney had apparently taken place only about three days before death, *i.e.*, at the time she had complained of the cramps.

Some Unusual Cases of Leukæmia, with Demonstration of Stained Specimens of the Blood.—Dr. Theodore Janeway reported five cases of lymphatic leukæmia, four of which had been seen in his father's consulting practice. The fifth had been seen recently in dispensary practice, and he had been able to obtain a partial autopsy. Two of the cases should be classified as acute leukæmia. The first case occurred in a man aged thirty-eight years, who had had severe malaria two years before the onset. There had been a prodromal period of two weeks, during which he had felt tired. The onset had been marked by severe pain in the left side, and during the first week there had been uncontrollable epistaxis. Later on petechial spots had appeared on various parts of the body. There had been some rise of temperature. When seen, four weeks after the commencement, there had been marked pallor; an enlargement of the spleen down to the umbilicus; slight enlargement of the cervical and inguinal lymph nodes, and slight enlargement of the liver. The blood count showed 840,000 red cells and 77,000 white cells. In the stained specimens it was evident that fully ninety per cent. of the white cells were mononuclear cells without granulations. There were a few myelocytes, megaloblasts, and normoblasts. No mast cells had been found. Death had occurred about two weeks afterward, the total duration of illness having been six weeks and a half. The second case was that of a child aged four and a half years, who had been seen in the University clinic. There had been diphtheria and scarlet fever two years before, and these had been followed by suppurative otitis. As the child had been on Long Island it had been treated at first for malaria. Six weeks before death there had been enlargement of the abdomen with considerable tenderness of the left side. Two weeks later there had been a hemorrhage from the nose and bowel. The blood count had not been made. When seen by the speaker there had been marked pallor of the skin and mucous membrane, with a lemon tint to the skin. The temperature was 101° F., and the pulse was very rapid. The spleen was enlarged down to the umbilicus, and extended well around into the flank. The liver was one finger's breadth beneath the free border of the ribs. The cervical and inguinal lymph nodes on the left side had been very slightly enlarged. The ophthalmoscope had shown a pale retina with numerous large, red-blotched hemorrhages. The blood examination showed very many large red cells present, but scarcely any poikilocytosis. The proportion of white cells was about one in twenty. There was a total of ninety-seven per cent. of lymphocytes. There was a little over two per cent. of multinuclear cells. There were also a few myelocytes, megaloblasts, and normoblasts. One week before death there had been persistent vomiting and bleeding from the gums and from the nose. At this time the abdomen diminished markedly in size. The child had died four months from the beginning of the attack, and six weeks after the onset of acute symptoms. The abdominal organs had been removed the day after death. The spleen reached only to the free border of the ribs, and had shrunk more than one-half in the last week of life. Both the liver and the kidneys were extremely pale, and the surface of the latter was covered with numerous hemorrhages. The marrow of the rib was pink. He had been unable to obtain the shaft of one of the long bones. Peyer's patches in the intestine were swollen and ecchymotic. The mesenteric glands were somewhat enlarged. The next case had been that of a man, seventy-two years of age. The first sign had been enlargement of the spleen, and this had steadily increased up to the time of death. Four months after enlargement of the spleen the cervical, submaxillary, and inguinal lymph nodes had enlarged. At the time of coming under observation the spleen had reached two inches below the umbilicus. The liver reached four inches below the free border of the ribs. There had been no fever, and no heart murmurs. Two or three blood counts had been made. The hæmoglobin had been about sixty-five per cent., and the red cells had never been below 4,500,000. There was over nine per cent. of large uninuclear cells. It had been noted that the cells took up Ehrlich's nuclear stain with great difficulty. Death occurred nine months after the first symptoms, from pneumonia. The next case had been that of a man between fifty and sixty years of age, who had gradually emaciated for nearly a year before his death. The spleen had been very markedly enlarged, and the inguinal, abdominal, and axillary lymph nodes had also been enlarged. The blood showed the ratio of at least one white to five red cells, and of the white cells over ninety per cent. were small lymphocytes. There were no mast cells, myelocytes, or eosinophiles. Death had occurred in a little over one year. The fifth case had been that of a man fifty-seven years of age, who had had the grippe three years before, followed by slight enlargement of the cervical and axillary glands. Nineteen months before death the lymph nodes on each side of the neck had begun to increase in size, and at the same time blood clots had been passed in the urine. The latter was explained by an ulcer in the urethra. Several times bacilli resembling tubercle bacilli in appearance had been found in the sediment from the urine, which had not been decolorized by remaining twenty-four hours in alcohol. The enlargement of the neck had been so great that the neck had measured nineteen and one-half inches in circumference. The spleen had reached to three fingers' breadth below the ribs. The liver had been only slightly enlarged. The hæmoglobin was thirty-five per cent.; red cells 2,000,000, and white cells 418,000. The white cells were over ninety per cent., almost all being of the small variety. The duration of the illness was seven months. The speaker said that the most interesting feature of these cases was that the count of the white cells had apparently run parallel with the duration of the disease, the cases having the highest count of white cells having lasted the longest.

Dr. E. Libman said that he had seen five cases of acute leukæmia, and they had been of a very different type from the chronic ones. The term "acute lymphocythæmia" seemed to him a much better one. In the cases that he had seen, the white cells had consisted, for the most part, of uninuclear cells, which ranged from the size of the red corpuscle to twice that size. There was but little protoplasm about the nucleus, and the nucleus stained poorly and was poor in chromatin. The multinuclears were relatively, and sometimes absolutely, diminished in number, and the eosinophiles were very few. Fränkel had described such cases. The first case that he had seen had been that of a child who had been admitted to the Mount Sinai Hospital after an illness of a few weeks. At that time there had been moderate enlargement of all the lymphatic glands, a very large spleen, and hemorrhages all over the body. He had been impressed at that time with the fact that the red cells showed the characteristic picture of pernicious anæmia. Otherwise the picture was that of an acute leukæmia. Many of the white cells appeared to be degenerating. Two days later the white cells had decreased very markedly. Corresponding to this, the spleen and the lymphatic glands had been reduced almost to the normal. Before death, the white cells numbered only 2,200, and the blood-picture was that of a pernicious anæmia. There had been a pneumonia present to which was attributed the regression of the leukæmic symptoms, as it was known that under the influence of acute infectious processes leukæmic changes ware apt to diminish. Another of the cases he had seen had resembled typhoid fever. In a third case, there had been two small abscesses, and, the contents of these consisted almost entirely of uninuclear cells. The fourth case had been that of a woman who had entered Mt. Sinai Hospital suffering from pneumonia. She had the color of pernicious anæmia, and had hemorrhages in the skin and from the gums. The white cells had not been increased greatly, but had been of the type described. It was considered that the patient was suffering from an acute leukæmia which was regressing because of the pneumonia, and an unfavorable prognosis was made. The pneumonia resolved entirely, but the patient died some days later. Dr. Libman said that he had reason to believe that the symptoms and blood changes in an acute leukæmia could regress without the presence of an infectious process, and that such regression would have to be explained theoretically by an exhaustion of the bone marrow, due to the hemorrhages.

Dr. James Ewing said he could accept three of the cases as rather typical, but the eivdence in the first two cases of acute lymphatic leukæmia seemed incomplete. In the first there had been a moderate number of myelocytes and megaloblasts. The anæmia had been severe, and there had been no autopsy. Moreover, the lymphatic enlargement had been very slight. Such evidence seemed to him insufficient to establish the diagnosis. Myelocytes were almost unheard of in lymphatic leukæmia—it was a diagnostic point. The megaloblasts were usually very scarce; from the mild stages of the chronic cases up to the termination of the disease the absence of megaloblasts was quite characteristic. The lymph nodes were usually the chief seat of the lesion, and were very prominent, yet in this case they had been but very slightly affected. While, therefore, he would not say that it was not a case of acute lymphatic leukæmia, there was good ground for hesitating to accept that diagnosis. In the second case, megaloblasts had been present; the spleen had been extremely small, as had also been the intestinal lymph nodes. The absence of any distinct indication of hyperplasia of the lymphatic structures was a strong point against acute lymphatic leukæmia. He understood that there had been a considerable enlargement of the liver during life—even more marked than that of the spleen—while the blood had shown the white cells to be not small lymphocytes, but large uninuclear cells. He would not, therefore, classify the case as one of acute lymphatic leukæmia, but rather as one of von Jaksch's anæmia. He had seen over one hundred thousand leucocytes in a case of diphtheria in a child, over ninety per cent. of which had been small lymphocytes. He would not make a diagnosis of acute lymphatic leukæmia unless the lymphatic structures were very much enlarged, or the blood changes very distinct, or until he had made a microscopical examination of the bone marrow. It was beginning to be recognized that the separate types of leucocytes had nothing to do with one another. In typical cases of lymphatic leukæmia the small lymphocytes were the ones specially increased, yet on examining the slide presented it seemed to him that the small lymphocytes were hardly increased at all.

Dr. Libman said that from the examination of the blood slide from the second case, he thought there could be no doubt that it was a case of acute leukæmia. These cases were entirely different from lymphatic leukæmia. The term "acute leukæmia" was introduced to describe cases in which there existed fever, hemorrhages, enlargement of the spleen and lymphatic glands, involvement of the bone marrow; and Fränkel had shown, in 1895, that the blood changes found were such as appeared in the specimen under the microscope, and that all these changes could disappear to a large extent before death. He had himself seen two cases in which the phenomena had almost entirely disappeared before death, yet the bone marrow presented typical changes at the autopsy. The slide, together with the history, made it clear that the case was one of acute leukæmia, according to the description given by Fränkel.

Dr. Janeway, in closing, said that in the first case the spleen had decreased from one-half to three-fourths during the last few days of life. By comparing the size of the mesenteric lymph nodes as found at autopsy with the clinical record it seemed evident that the lymph nodes had diminished in size in proportion to the diminution in the size of the spleen. It had been recently suggested by Minkowski to make three classes of leukæmia, viz.: (1) Ordinary chronic leukæmia, beginning rather acutely, remaining stationary for some time, and having a considerable duration; (2) acute leukæmia, having the primary lesion in the bone marrow, just as in the first class, but associated with enlargement of the spleen and of the lymph nodes and lymphatic apparatus elsewhere, and running a very rapid course, sometimes only a few days, and associated with fever and hemorrhages; and (3) the chronic lymphæmias—the class specially referred to by Dr. Ewing. The classification of von Jaksch's anæmia had seemed to him specially indefinite. A number of cases had been recorded of transition from von Jaksch's anæmia to acute leukæmia. There was one case on record of transition from pernicious anæmia to acute leukæmia. In his fifth case, which Dr. Ewing did not question, the cells had not all been of the small lymphocyte type. The presence of megaloblasts in the acute cases had been thought to go hand-in-hand with the acute anæmia.

Demonstration of Specimen Showing the Growth of the Tubercle Bacillus on Hesse's Medium.—Dr. Robert J. Wilson said that Hesse's medium was supposed to be peculiarly favorable for the growth of tubercle bacilli, and depended for its efficacy upon a special food-stuff. It was claimed that the tubercle bacilli would grow on this in a few hours, so that their vitality could be proved or disproved very quickly. The medium was also useful in cases in which the growth of the bacilli was not very characteristic. Dr. Wilson said that he had made a series of seventeen plates, and growths had been obtained on nine of these. Trials had been made on blood serum and on ordinary agar-agar, and with the exception of one there had been no growth at the end of forty-eight hours. In the exceptional case there had been a small growth limited to the borders of the cell. He had observed that the growth in the plates seemed to start in some of the material carried on to the plate at the time the culture was made. This led him to think that it was highly probable that the growth always first started in such material, and then, finding the medium favorable, further growth was able to develop on it. The material transferred to this plate was necessary for the starting of the growth, in very much the same way as blood was necessary for starting cultures of the influenza bacillus. Hesse thought it probable that the tubercle bacillus divided in its longitudinal axis, which was, of course, contrary to the general belief, yet a study of these plates which he had prepared afforded some ground for such belief.

Dr. Hiss said that he had had experience in only four cases in the growth of bacilli from sputum on Hesse's medium. In all of these he had obtained a growth which had continued for from twelve to fourteen days, after which the colonies had developed very slowly. One plate had been under observation for two months. He had seen nothing to make him think that longitudinal division occurred. The organisms were pressed out of the advancing line along the line of least resistance. It might be that material carried over had something to do with the starting of the growth. The medium might be of service in the rapid differential diagnosis of organisms presenting the same staining characteristics.

Dr. L. A. Conner asked whether the tubercle bacilli grew very much more rapidly on Hesse's medium than the other bacilli found in the sputum.

Dr. Hiss replied that the contaminating organisms from the sputum did not seem to grow so well on Hesse's medium as did the tubercle bacilli. This was one of the chief advantages of the medium.

Dr. Wilson explained that his work had been done with pure cultures from guinea-pigs, so that he had had no contaminating organisms.

Dr. Hiss said that the specimens that he had had under observation for two months had not been overrun in this way, and in the others the colonies were still discrete. Hesse had taken great pains to secure bacilli from material as free as possible from contamination.

Dr. Harlow Brooks said that he had seen four plates by Dr. Hesse from sputum which contained a good many streptococci and staphylococci. The contaminating organisms had been found comparatively common in the smear, while the tubercle bacilli had not been very numerous. About forty-eight hours afterward the colonies of tubercle bacilli were strikingly evident, while the growth of the contaminating colonies had not been very marked. Two or three days later the contaminating colonies had overrun the tubercle growths.

A Case of Intestinal Tuberculosis in a Child.—Dr. D. Bovaird reported the case of a boy aged three years who had been returned to the New York Foundling Hospital last August in accordance with the rules of that institution. He had then been sent to the home at Spuyten Duyvil and had remained in fair health until October 24th. At this time, during an epidemic of measles, he had developed this disease, and it had run the usual course. For a whole month the temperature had been very irregular, and the symptoms had indicated a severe bronchitis or broncho-pneumonia, although the physical examination failed to show pulmonary consolidation. During this time there had been a severe stomatitis, though this had improved slowly. At the end of November the evening temperature had been 100° to 101° F. After about two weeks more of this irregular fever the child had developed the first enteric symptoms. About December 15th the condition of the mouth had again become worse, and had soon changed into a true cancrum oris. It was in this condition that the child had been returned to the Foundling Hospital. Death had occurred from the exhaustion incident to this. On December 20th the child had died, and the autopsy had been made on the following day. The pharynx, trachea, and bronchi were normal. Both pleural cavities, except anteriorly, had been obliterated by adhesions. The bronchial nodes contained a few minute caseous foci. The lungs themselves were normal. The peritoneal cavity had been obliterated by adhesions, and the intestine and all the other viscera were matted together by adhesions. The peritoneum was thickly studded with miliary tubercles. The peritoneal surface of the liver was covered with miliary tubercles, but only a few were found in the hepatic tissue. The same condition was found in the spleen. The kidneys, suprarenals, pancreas, and stomach were normal. Peyer's patches were swollen and contained numerous ulcers which reached to the peritoneal coat. In the upper part of the large intestine were a few caseous nodules. The solitary follicles were enlarged throughout and somewhat ulcerated. The bladder was normal except for slight congestion. The mesenteric nodes were enlarged, and some of them showed caseous foci. Among the records of the Foundling Hospital were those of two hundred autopsies on cases of tuberculosis in children, yet in only three was there a fair presumption that the intestine had been the primary seat of the infection. For this reason the case just presented was of special interest. Furthermore, when tuberculosis had developed immediately after measles he had usually assumed that it was nothing more than a lighting up of a previously received tuberculous infection, but in the present instance the diffusion of the lesions through the small intestine, taken in conjunction with the history of the case, made it not improbable that the tuberculous infection had developed subsequently to the measles.

Dr. Ewing thought the development of tuberculosis after measles was too common to make it probable that the tuberculous infection always occurred after the measles. Regarding the condition of the Peyer's patches it should be borne in mind that these were really excretory organs, and might possibly, under certain circumstances, suffer from the excretion of tubercle bacilli. He had recently seen for the first time cases of intestinal tuberculosis limited entirely to Peyer's patches. He had formerly supposed that tuberculous ulcers were almost invariably irregular, and that their long axes were in the transverse diameter of the intestine. In some recent cases the ulcers had been confined to Peyer's patches, which had been deeply excavated. It seemed possible that the bacilli might sometimes be deposited here by the blood current or by the lymph current, instead of from the intestinal contents.

Dr. Bovaird said that the child had been fed on milk obtained from an excellent source. Up to the very last the child had had a diarrhœa, yet the stools had never contained blood, only mucus and undigested food.

Dr. Martha Wollstein said that autopsies had been held at the Babies' Hospital on some hundreds of cases. Probably fifteen per cent. had been on tuberculous infants, yet in few of these children during life had bloody stools been present, so that they had come to look upon this as a rare symptom in young infants. At that hospital they had never met with a single case in which it seemed at all clear that the infection had been primary in the intestine, even in infants fed on bad milk. In the case under discussion it seemed impossible to prove that the tuberculosis had not been primary in the bronchial nodes. Its rapid extension along the intestinal tract was possibly due to the condition of that tract (a previous catarrhal condition of the intestine), thus furnishing a line of least resistance, and explaining the localization.

A Case of Acute Tuberculous Broncho-Pneumonia.—Dr. E. Hodenpyl presented specimens from a case of acute tuberculous broncho-pneumonia in which death had occurred on the twelfth day of the disease. The symptoms and physical signs had resembled very closely those of acute lobar pneumonia. The gross lesions of the lung could hardly be distinguished from those of a simple case of broncho-pneumonia. The short duration of the disease was very remarkable. The shortest recorded case of pulmonary tuberculosis of which the speaker was aware was eleven days. The subject was a colored woman, who had been taken sick with pain in the left chest, cough, prostration, and fever. After remaining in bed five days she had been removed to the hospital, and examination had shown apparently an ordinary pneumonia involving the whole lung. The temperature fell rapidly in two or three days from 105° to 96° F., and in a few hours rose again to 105°. At this time evidence of consolidation had been discovered on the opposite side. She died on the twelfth day. At the autopsy, the left lung, which was free from pleurisy, was studded with larger and smaller pneumonic patches arranged about the bronchi. These were so numerous as to cause the lung to appear almost solid. The pneumonic patches except in one or two instances failed to show any cheesy degeneration. The right lung presented the same lesions as the left, though developed to a less degree. Stained smears from the pneumonic exudate showed tubercle bacilli in enormous numbers.

Dr. Prudden asked if there was any clew as to the possible source of the infection.

Dr. Hodenpyl replied that he could find none. Evidently this was a case of aspiration tuberculosis from the bronchi. No old tuberculous focus had been made out.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, February 12, 1900.

Charles N. Dowd, M.D., Chairman.

False Joint after Old Fracture and Dislocation of the Elbow.—Dr. Forbes Hawkes presented a boy aged thirteen years who, when eight months old, had fallen and injured his left elbow. At that time it had been treated for a time with plaster of Paris, but shortly after the removal of the dressing he had hurt the arm again. This second injury had not been treated. The arm was now strong and useful, but there was a slight deformity over the inner condyle. Examination showed the left upper extremity to be slightly shorter than the right. In the extended position the internal condyle could be felt projecting, and there was a movable bony mass above and attached to the head of the radius. Flexion and extension were possible to practically the normal limits. Apparently a new joint had been formed between the outer fragment and the humerus itself. The case was of interest because of the unusually good functional result, considering the nature of the original injury. The condition of the joint was shown by radiographs. No operation was advised.

Dr. T. H. Manley was inclined to believe that the olecranon was in its proper position in this case, that the protrusion above was due to the enlargement of bone, and that the olecranon moved on the proper articular surface of the humerus. He had seen a number of similar cases in which there had not been really a false joint, and he did not believe that the *x*-rays gave much assistance in such a case.

Dr. Reginald H. Sayre thought if an *x*-ray photograph should be taken in the antero-posterior direction, with the arm in an extended position, it would clear up the point raised by the last speaker.

Dr. Hawkes replied that one of the radiographs had been taken with the arm perfectly extended, and this seemed to him to demonstrate the existence of a false joint. Regarding the interpretation of *x*-ray photographs he would say that he had recently had a case of Colles' fracture with typical deformity, which, after its reduction, had failed to show in an *x*-ray photograph any evidence of fracture.

Round-Celled Sarcoma of the Testicle. — Dr. Pfister presented a man, twenty-five years of age, from whom he had removed a large round-celled sarcoma of the testicle. One testicle had not descended, but in this instance it was the descended testicle that had become malignant.

DR. JOHN B. WALKER said that, of a number of ectopic testicles reported in the literature, a considerable percentage had developed sarcomatous change. This was one of the reasons for urging operation on the undescended testis.

Acute Intestinal Obstruction; its Diagnosis and Treatment.—DR. PARKER SYMS read a paper with this title. He said that there were two main classes of this disorder, (1) in which there was not only an occlusion of the intestinal canal, but a condition of strangulation, and (2) those in which the fecal flow only was arrested. The vast majority of cases of acute intestinal obstruction belonged to the first class, or, in other words, were attended by acute intestinal strangulation. Acute intestinal obstruction and strangulation, as in the case of a strangulated hernia, must be looked upon as absolutely fatal, unless promptly relieved by operation. This condition was due either to intussusception, volvulus, constriction by bands, escape of a loop of intestine through some normal or abnormal aperture, pressure by a tumor or displaced organ, or impaction of some foreign body. Of course, any case of chronic intestinal obstruction might become suddenly one of acute obstruction. For most practical purposes it was proper to assume that the strangulation was associated with acute obstruction of the bowel. Strangulation meant that a great injury had been inflicted upon the nerves of the solar plexus. This gave rise to abdominal shock—a condition which stamped these cases early and most emphatically. This fact should enable the general practitioner to differentiate early between true intestinal obstruction and mere constipation. The more important symptoms were pain, vomiting, constipation, tympanites, scanty urine, and the train of symptoms which went to make up the picture of abdominal shock, *i.e.*, small, rapid pulse, drawn and anxious face, perspiration, and a peculiar mental condition of combined fear and braggadocio. The vomited matter at first would be the contents of the stomach; later, it would be gastric mucus mixed with bile, and still later there would be stercoraceous matter vomited. The constipation would be absolute, and the tympanites would increase. Hiccough might come on at any time. As to treatment, the condition being a mechanical one, it could be removed only by mechanical means. Cathartics should never be employed, because they could not relieve the condition, and might seriously augment the pressure and even cause rupture of the bowel at the weakened point. High enemata might be given, but operation should not be postponed any great length of time. The incision should be in the median line, and the distended intestine should be systematically inspected in the search for the site of the obstruction. This having been found, it must be dealt with according to the conditions found to be present. In some cases the exhausted state of the patient would allow of only a palliative operation, such as the hasty establishment of an artificial anus. When the vomiting was almost constant and projectile in character, there was always danger from using a general anæsthetic. The use of opium in these cases was most dangerous until operation was about to be done, but at that time it was useful, as it was an excellent abdominal stimulant. The author's conclusions were: (1) Acute intestinal obstruction was a fatal condition, if not promptly and properly relieved; (2) acute intestinal obstruction should rarely be fatal if promptly recognized and treated; (3) acute intestinal obstruction was a mechanical condition, and could be relieved only mechanically; (4) the symptoms of acute intestinal obstruction were absolutely characteristic and distinct, and the diagnosis could always be made, unless the clinical picture had been obscured by the administration of opium; (5) an early laparotomy, properly performed, was the only plan of treatment which should be relied upon in this class of cases.

DR. A. A. BERG called attention to one pathological condition coming on after the second or third day in these obstructed cases, viz., an intense and rapidly progressive emaciation. He had at first supposed this to be due to the shock arising from the involvement of the sympathetic plexus, but he was now inclined to think that the intense pathogenicity of the imprisoned micro-organisms was the cause. The question had often occurred to him, whether it was wise to proceed to a resection of the bowel, even granting that the patient's condition was good. Such resection, together with an intestinal anastomosis, would mean that the bowel must be kept at rest for two or three days afterward. This would mean that the organisms in the proximal loop of the intestine would be draining the system constantly. He was of the opinion that our statistics would be far better if, under such circumstances, the artificial anus was made at the time of the first operation, and a large tube was introduced into the proximal and distal loops of the bowel, and the latter washed out with saline solution. A rather early secondary operation could be undertaken for the relief of the artificial anus. This plan seemed to him better than immediate resection and approximation. He had had very good results from infusing the patients every hour with saline solution. He had seen patients pulseless at the time of making an artificial anus kept alive for several days by these repeated infusions, so that it seemed possible that life might be saved by the same treatment.

DR. MANLEY said that he had never seen a case of acute intestinal obstruction in which the patient survived twenty-four hours, if not operated upon. He called attention to the fact that practically the same symptoms would be observed in a case of perforation of the bowel as in one of acute intestinal obstruction. The chief difference would be in the absence of hepatic dulness in cases of perforation, because of the diffusion of gas upward. A case was mentioned in which, though the symptoms had been very acute and had lasted only a few hours, the use of a high enema had resulted in the escape of the fluid through the gangrenous portion of the bowel into the general peritoneal cavity.

DR. H. J. BOLDT narrated the case of a child aged twelve years who had been operated upon for perforative appendicitis and a general peritonitis. The operation had been done last July. The girl had recovered with a fecal fistula, which had healed spontaneously in a few weeks, and had remained so up to a few days ago. When she had been seen on February 5th there had been vomiting and abdominal pain, a pulse of 110, and a temperature of 101 4° F. A high enema had been given at once, but with no relief. On the following day most of the symptoms had abated, and the general condition had been better. It was assumed that the intestinal obstruction was due to a band from the previous peritonitis, and owing to the excellent general condition and the absence of tenderness to the left of the umbilicus and on a level with it, delay had seemed justifiable. On the next day the pulse had been normal, and the temperature nearly so, but there had been a suspicious point of resistance, and a little stercoraceous matter had been vomited. Abdominal section was therefore done promptly, and, to his surprise, considerable peritonitis was already present. The obstruction was found to be due to a band. About eight inches of the bowel had been resected and an anastomosis established. So far, the child had done well. He had operated upon another case early that morning—that of a child aged seven years. The history had been absolutely typical of an acute intestinal intussusception, but on examination he had found a large swelling in the epigastrium, which had led him to doubt the correctness of this diagnosis. Owing to the great urgency of the symptoms he had hastily made an exploratory incision, but had found nothing but a very greatly enlarged liver. That child had died within a few hours, but he had been unable to explain the symptoms of intestinal obstruction. One speaker had referred to the necessity for keeping the bowel quiet for a few days after these intestinal operations, and this led him to say that he had not made it a practice to do so, and had seen no reason to regret having adopted this course.

Dr. A. Ernest Gallant mentioned a case of volvulus in which he had relieved the early bilious vomiting by the use of plain water and nitroglycerin. He had desired to operate, but several consultants had advised against it. Death had finally occurred, and the autopsy had shown the cause to have been a volvulus. According to his experience most patients in cases of acute intestinal obstruction did not die under five or six days. In post-operative cases of intestinal obstruction, relief might often be afforded by massage of the bowel, and when this did not succeed he felt that immediate operation was imperative.

Dr. Willy Meyer said that the gut should always be opened above the seat of obstruction at the time of operation, and the contents of this portion should never be allowed to pass on downward. The evacuation of the matter contained in this portion could be readily effected by making either a transverse or a longitudinal incision into the bowel. This should be the rule with every surgeon before attempting to reduce the intestine into the abdominal cavity.

Dr. Syms said, in closing, that he had endeavored to show in his paper the possibility of making an early diagnosis, and the probability of securing a good result from early operative interference. It was most important, therefore, to throw into the background the exceptional cases, which served chiefly to obscure the diagnosis and encourage fatal hesitancy. He was disposed to follow Dr. Boldt's advice to move the bowel early, even after resection and anastomosis.

The Hockey-Stick Incision—a Typical Mode of Entering the Abdominal Cavity in Certain Complicated Cases of Appendicitis.—Dr. Willy Meyer read a paper with this title. He said that at the present time in interval cases of appendicitis every surgeon tried to get along with as small an incision as possible. The effort should be made to restore the abdominal wall to its former condition. It was different in cases of acute appendicitis, in which very free access to the abdominal cavity was often essential. The incision parallel to the outer side of the rectus muscle was now rarely employed; the majority of surgeons when operating for acute appendicitis preferred to make the incision very near the anterior superior iliac spine, where the abdominal muscles were the thickest. The trouble here was to decide upon the best mode of enlarging such an incision should it become necessary. Many surgeons would abandon the first incision, and make a second one in the median line; others would make a more oblique incision without regard to the direction of the fibres of the external oblique muscle. The speaker said that, in the course of his operative work in appendicitis, he had found a very useful incision—the one described in the title of this paper. He had discovered that an incision in the direction of the fascia of the external oblique should begin exactly midway between McBurney's point and the anterior superior spine, and then continue in a straight line downward to a point at which the femoral artery was found pulsating under Poupart's ligament. In ninety-five per cent. of the cases such an incision would correspond with the direction of the fibres of the fascia of the external oblique. In most cases of acute appendicitis he began the incision half an inch above and midway from McBurney's point and the anterior superior spine of the ilium, and ended it from half to three-fourths of an inch from Poupart's ligament. He first ascertained where the femoral artery was pulsating under Poupart's ligament, and then cut toward this point. His practice was to enter the peritoneal cavity at the lower end, and, with his finger inside as a guide to the position of the epigastric artery, enlarge the incision downward and inward in a curved direction. This gave to the whole incision the shape of a hockey-stick; hence the name. The incision was exceedingly useful in intrapelvic operations. Even the left Fallopian tube and ovary could be palpated by two fingers passed through this incision. The upper or straight portion of the incision might be closed with tier sutures, and the lower portion left for drainage, although sometimes it was desirable to insert one or two sutures in the extreme lower angle of the curved incision.

Dr. John F. Erdmann said that some years ago he had employed an incision having a similar curve, and had found it exceedingly useful for exploring the pelvis. It seemed to him that it should not be necessary to cut through the conjoined tendon; it should be possible to separate this structure.

Dr. Joseph Wiener said that he could not quite agree with Dr. Meyer that most surgeons, in cases of appendicitis, cut through the thickest portion of the abdominal muscles; the majority, he believed, now avoided dividing the muscles as had been done eight or ten years ago, preferring to use Kammerer's incision through the rectus muscle. One point in favor of this incision was that one did not know, even in interval cases, just where the appendix would be found. An incision along the border of the rectus muscle, which could be enlarged upward or downward *ad libitum*, seemed to him the most valuable for the great majority of cases.

Dr. Meyer said that by means of an incision near the anterior superior iliac spine it was possible, in almost every instance, to reach the appendix, no matter where the latter was situated. In cases of acute appendicitis he was particularly opposed to the incision at the border of the rectus, not only because such an incision did not give the freest access to the appendix, but because it involved the division of the nervous supply of the rectus, and therefore caused paresis of this muscle.

Strangulated Omental Tumor.—Dr. C. H. Peck exhibited a tumor made up of the entire omentum. This had been found rolled up in a vertical direction, and filling the right side of the abdomen from the umbilicus down to the pelvis. It projected behind the uterus and to the right, and pressed well into the anterior fornix of the vagina. The woman gave a history of having been in her usual health up to four or five days prior to admission to the French Hospital. She had then been attacked suddenly with abdominal pain and vomiting, associated with a moderate rise of temperature. On admission the temperature had been 100.5° F., and a mass could be made out indistinctly in the abdomen. On performing abdominal section, this solid tumor had been found. About two inches below the transverse colon a very tightly twisted pedicle had been discovered. This had proved to be the entire upper portion of the omentum twisted around the vertical axis. The symptoms had evidently begun when the strangulation of this portion had been produced by the twisting.

"The Journal of the Medico-Chirurgical College" of Philadelphia is the title of a new monthly journal, under the editorial charge of Dr. John A. McKenna.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MILITARY MEDICAL SERVICES—THE EPIDEMIC—THE REGISTRAR-GENERAL—SALOL IN SMALLPOX—GLAUCOMA CAUSED BY MYDRIATICS—EPIDEMIC DIARRHŒA—MIDWIVES BILL—INCREASE OF PROFESSION—DEATHS OF SIR T. G. STEWART, DR. TURNER, AND MR. ADAMS.

LONDON, February 9, 1900.

THE rude awakening of the public to the inefficiency and criminal blundering of the War Office may perhaps lead to an improvement of the medical department. Already there is some anxiety as to the deficient number of the Royal Army Medical Corps manifest at Aldershot. A correspondent there says it is a very grave question where the details of this corps are to come from for the thirteen thousand men leaving our shores for active service by Monday next. All that are at present left at Aldershot are the details for the eighth division and less than fifty men outside the recruits under training. A reinforcement of the corps by at least one hundred officers is urgently needed to meet the necessities of the service, but the military authorities go on groping in their purblind way of routine. A "competitive" examination has been advertised for thirty vacancies, and only twenty-five candidates are ready to compete! Competition indeed!

On Tuesday the War Office notified that men of the Volunteer Medical Staff Corps and bearer companies of the volunteers who joined the Royal Army Medical Corps would receive the same pay, allowances, and other gratuities or privileges of the R.A.M.C.

The condition of the militia is also causing anxiety. As this force has been neglected in nearly every other department, it is not to be wondered at that the medical has got near the vanishing-point. On the part of the authorities it is asserted that twenty-four medical officers are still serving with the militia. These must be fast nearing the age of retirement, and are those who have survived of the two hundred and fifty attached to this force before the change from the regimental system. Some forty years ago the army medical officers with those of the militia were nearly fourteen hundred in number. Now they do not muster nine hundred. Everything connected with the defence of the country is now occupying public attention, and the indignation expressed as to other negligences is likely to be extended to that concerned with the sick and wounded.

Influenza continues to decline steadily, as seen in the mortality returns. In the last week the number of deaths registered from the epidemic fell to one hundred. It was a contributory cause in fifteen other deaths, but in this class the fall is just as marked. The death rate of London from all causes fell last week to 19.6, and in this total rate the decline has been steady. For the preceding three weeks the figures were 33.3, 26.9, and 22.2. In the thirty-three great towns the rate averaged 21.2, the highest being 35.4 at Sunderland, the lowest 12.6 at Derby. At Nottingham, which I mentioned a month ago as having reached 44.9, it has declined to 18.3.

Speaking of registration reminds me that a new registrar-general has been appointed in place of the retiring one. There were a certain number of people who thought that in the fitness of things the authorities would appoint a medical man to the office. They counted their chickens too soon. What matters that medical knowledge is the proper qualification for appreciating the many questions that arise in the registration of deaths? What matters the lessened scientific importance of the statistics? The berth was too good to be given to a mere doctor, when a hundred greedy hands were stretched out to every one who had any voice in the selection or recommendation of a candidate.

The salicylates at one time were employed, perhaps, on a more extended scale than of late. In all sorts of fevers some of them were tried. Pridaux treated eighty-eight cases of confluent smallpox by salicylates without one death. That was in 1878. Since then I have heard of no such success, though perhaps the treatment is still employed in some places. Dr. Charles Begg last month communicated to one of the Edinburgh medical societies his experience in China, where he treated the disease with salol, acting on inferences he drew from observation in patients taking the drug for other conditions. A patient with cystitis took a drachm daily, and though he had hundreds of mosquito bites they gave him no trouble; there was no swelling, redness, or irritation. Yet before taking the salol the man suffered much from the mosquitos. Dr. Begg inferred an anæsthetic effect on the skin, and proceeded to try salol in smallpox. He admits that there was some mental depression, but not enough to account for the freedom from skin irritation. In smallpox, he says, salol almost always prevented the vesicles from becoming pustules, and when it was used early no pocking occurred. The patients had no desire to scratch the skin, so the danger to the eyes was greatly lessened. The freedom from cutaneous irritation also allowed the patients to sleep and so prevented exhaustion. No ill effects were noticed when doses of a drachm daily were continued for long periods.

Dr. Begg attributes to the drug an anæsthetic effect during elimination by the skin, but we have no evidence that elimination through this channel takes place; it is certainly not the usual course. He says, too, that the foul odor of variolous patients was masked by a fruity odor, which he infers is due to the elimination of the salol by the skin. The observation is interesting, whether the inference be correct or not.

Dr. Norman Walker said his experience with salicin in skin diseases supported Dr. Begg's observations with salol.

Glaucoma may follow a single instillation of homatropine. Mr. Shears reported such a case to the Ophthalmological Society. It occurred to a woman aged fifty-two years, who at the Liverpool Eye and Ear Infirmary had one or two drops of a solution, four grains to the ounce, put into her right eye, and a week later returned with all the signs of acute glaucoma, rendering iridectomy necessary. Mr. Shears said he thought no mydriatic should be used in patients over the age of thirty without very careful consideration. If homatropine were used it would be well to instill eserine before the patient left the hospital; cocaine followed by eserine was usually sufficient for ophthalmoscopic examinations, or euphthalmin, the new dilator, would be satisfactory.

Only a few cases have been reported by specialists, but it is of importance to the general practitioner, who often uses mydriatics, to remember the possibility of this untoward effect.

The Royal College of Physicians has adopted the recommendation of its committee appointed last summer on the certification of deaths from diarrhœa. It appeared that a number of different terms were employed by practitioners to designate epidemic diarrhœa, leading to confusion in the registration returns, and perhaps confirming the public in the notion that diarrhœa is not dangerous. The college, therefore, recommends that the term "epidemic enteritis" should be uniformly employed, to the exclusion of gastroenteritis, muco-enteritis, gastric catarrh, etc.

We are again to be troubled with a midwives bill. It has been put down for the 28th. Happily the miners' eight-hours bill has the first place for that day, so perhaps the midwives may be lost for want of time.

The subscribers to the Medical Directory have received their copies. The issue was delayed by a fire at the printing-office. From the statement of the editors the number of names included is 35,651, being an increase of 534 on last year's numbers; and that is an increase of 6,127 in the last ten years. An overcrowded profession—but the numbers still rising!

You will regret—doctors in all countries will regret—to hear that Sir Thomas Grainger Stewart has succumbed to the illness to which I have more than once referred. He died on Saturday last, February 3d, in his sixty-third year. The end was rather unexpected by many, though it was generally known that it might occur at any time, although he had not long before been able to drive out. In youth he had had rheumatic fever with cardiac complication, and in 1882 he was again attacked, pericarditis being severe. He returned to work, and in 1891 had influenza, which left the weakened heart much worse. Last year a pleuritic attack necessitated paracentesis. The valvular disease proceeded, now better, now worse, as usual, and at length the heart quite failed. It is as a great clinical teacher that Sir Thomas Grainger will be first thought of by his pupils scattered all over the world, for he succeeded Professor Laycock in the chair of Physic of Edinburgh University as long ago as 1873, having previously been connected with the Royal Infirmary and the extra-mural school. He was born and brought up in Edinburgh, but after graduating he spent some time in study on the continent. Soon after returning he became pathologist and assistant physician to the Infirmary. For some time he lectured on pathology at the Royal College of Surgeons, where his remarkable teaching ability had full play. Those who have heard him speak in later years will readily understand that his eloquence, commanding figure, and profound learning, combined with a gift of humor, must have been most attractive to students, who found that he could make the dryest subject interesting. Once a man so gifted begins to teach, his steady rise in the estimation of colleagues and students may be safely predicted, and Edinburgh soon became proud of her professor. Other universities recognized his merits and gave him their degrees, and the College of Physicians made him president. Learned societies in various countries enrolled him in their membership. He was appointed physician to the Queen, and in 1894 was knighted. He was deputy-lieutenant of the city and county of Edinburgh.

Sir Thomas Grainger's chief medical treatise was that on "Bright's Diseases of the Kidney," which at once placed him in the front rank of renal pathologists, and the second edition of which appeared in 1871. In 1884 he published "An Introduction to Diseases of the Nervous System," and he had previously made several contributions to this class of diseases. Somewhat later came two "Clinical Lectures on Important Symptoms," issued separately. No. 1 was on "Giddiness" and No. 2 on "Albuminuria." But a man of Sir Thomas Grainger Stewart's breadth of mind and literary power would not be confined to medical work, and some two years ago he ventured to publish a drama in blank verse, "The Good Regent," and so he is numbered with the doctors who have dallied with the muse.

The death of Dr. Charlewood Turner will come as a surprise to many who looked to him for further contributions to pathology, for he was comparatively young and had certainly not reached the height to which he seemed destined. He graduated at Cambridge in 1874, joined the London College of Physicians the next year, and was elected a fellow in 1881. He was physician to the London Hospital, where for some time he taught pathology. To the International Congress of 1881 he contributed a paper on "Fibroid Degeneration of the Heart." He had previously read important communications at the Pathological and other societies, and at their meetings he was always listened to with the respect due to his extensive knowledge of pathology.

Last week I recorded the death of an aged orthopædic surgeon, Mr. Brodhurst. I have now to announce another still older, Mr. William Adams, who died on Saturday last, the eightieth anniversary of his birth, of bronchitis and pulmonary congestion. He took his diploma of M.R.C.S. in 1842, and the fellowship of the college in 1851. He won the Jacksonian prize in 1864, the subject that year being clubfoot, though his lectures on orthopedic surgery and on subcutaneous surgery were much earlier; in fact he was a frequent contributor to the press and societies from the fifties to the time of his retirement, for you will find an article of his on "Wry-neck" in the Transactions of the American Orthopedic Association for 1896. He was an ex-president of the Medical Society of London.

LETTER FROM NEW ZEALAND.

(From our Special Correspondent.)

AUCKLAND, January 17, 1900.

THERE are only three topics that occupy public attention here at present: First, the war; second, the influenza, and third, the appearance of the bubonic plague in South Australia, the Sandwich Islands, and New Caledonia.

The last is the most recent sensation. "Proximus ardet Ucalegon," and finding the fire so near us and in places with which we have constant communication, we have naturally taken the alarm. The sanitary authorities have ordered the inspection of all premises and the removal of filth. Of course this is rather late in the day, but better late than never. The death rate here is small, about eleven per thousand annually, and the people live well, and for the most part are temperate as to drink. It is probable that there will not be nearly so large a mortality from plague as there has been from influenza.

Influenza has been prevailing in every part of the colony during the last two or three months. The curious thing is that instead of commencing at one centre and spreading gradually to the rest of the colony, it broke out simultaneously in every part. This I cannot but attribute to the occurrence of election meetings. We are not plagued with many elections. We do not elect our judges or magistrates or local officials. We have only the municipal elections, and the general election for the House of Representatives. I don't know who the people are who take any interest in municipal elections. The general election, which takes place once in three years, does arouse some public interest, more, however, on account of the prohibition question than for any other reason. We have local option here to the fullest extent, and the vote is taken at the same time and place as that for the House of Representatives. Our upper house is nominated by the governor.

Very many crowded and enthusiastic meetings were held in every part of the colony during the three or four weeks preceding the election. These meetings were held in halls always badly ventilated, and, if ventilated at all, by open windows. Persons just recovering from influenza were there, poisoning the air. The people came out (it was our summer) bathed in perspiration, exposed themselves to the night air, for these meetings are always held at night, caught cold, and the cold took the form of influenza, with the usual characteristics. There was the sudden attack, the high fever, the complete anorexia, the cough, slight bronchitis, or in some cases gastro-intestinal catarrh, and above all the intense nervous prostration. This is so out of all proportion to the short but severe febrile stage, and lasts so long unless specially treated, that it forms the most important feature of the disease. Practically, in this relaxing and debilitating climate of Auckland, unless people can get away for at least a short time after an attack of influenza, the weakness will last for months. I have known cases in which the patient has complained, a year after the primary attack, of never having felt well since it occurred.

The disease is not fatal under proper treatment, but by careful selection of your doctor you may kill off speedily and without scandal an aged relative from whom you have expectations. I have found a treatment by small doses of liquid extract of cinchona, two to three minims every four hours of liq. strychninæ (P.B.), and whiskey, invariably successful. I have not yet lost a case. The whiskey I find very popular with prohibitionists.

The war absorbs about four-fifths of the public attention. We have already sent one contingent, and before this letter is posted a second one will have left. Our men have already undergone the baptism of fire, and three have been killed. We could send thousands, if they were not so mighty particular about the medical examination. It is very absurd to be so strict, as the men are engaged for only a year, and are mounted infantry. Now any man in fair health with a good constitution, and accustomed to an outdoor life mostly on horseback, may be taken as good for a twelvemonth, to do the same as he has been doing before. If he is a good rider and a fair shot, he is certainly good enough for the Boers to make a target of. I remember in the Crimean campaign having a lad aged eighteen years under my care, who had been only three months in the service, and who was wounded in four places before he had ever fired off his own rifle. And this grieved him. So he died.

It will give you some idea of the spirit that is animating our people to mention that it is more than hinted that political influence is brought to bear on the examining doctors, to induce them to reject some and admit others. I believe half our young men would go, for the mere love of a fight, if they could get the chance.

LETTER FROM SYRIA.

(From our Special Correspondent.)

Beyrout, Syria, January, 1900.

In speaking of our climate, we cannot say a word against the time that came between our summer and our winter. The months passed on the even tenor of their way. It was never cold, and—except, perhaps, of a sultry evening—only moderately hot. The famous mosquito came, carrying with him, no doubt, as everybody knows, his more famous parasite. But the weather did its duty, and the too-familiar insect took itself off before a storm, carrying its sucklings with it—and thus malarial types of fevers have been in abeyance.

These autumnal days of ours, too, they did the best of all; besides their action on the pests we mentioned, they cleared with a whirligig of purifying tempest—albeit, they nearly cleared us, too, off this promontory of ours—they cleared and cleaned the dens and lanes of filth and rubbish in many forms, and flushed the drains, and did such wonders with the rains from heaven that old men tell us here that never in their memory has this town been so empty, swept and garnished. It may have been the thunder and the lightning and the rain that did it. At any rate there was not a speck of mud nor the least small cloud of dust for at least three days.

So we woke up one morning to find our streets clean. And then for a time again there was nothing but dust and sunlight with mellow nights between, and with a drizzle or two old winter came on at last, letting the hardier ones of us off from the necessity of lighting fires in our houses to warm ourselves. From October till now, inside our homes the temperature has ranged from 64° to 62° F., with a minimum temperature of 52° F. outside. One night, however, we must admit the thermometer did drop to 56° F. in the house. The next morning there was a general complaint against the bleakness of the season, and many caught colds. It was a good thing for the profession here, as Beyrout had been previously presuming (as I heard it put by some one) to be so healthy that it might be necessary for medical men to raise their fees.

Be that as it may, this Eastern race, though subtle in instinct, is of a cool and calculating judgment, and they tell me that there is no need for either the Peculiar People or the Christian Scientists (so called) to come among them. These abnormalities would have small shrift in this Eastern town of ours, so the doctors are not likely to suffer from their invasion.

Healthy and all as we are here, there are two diseases abroad among us, and "we cannot wash them out": tuberculosis and typhoid. Strange that the former should exist in a land of sunlight and fresh air! We have the sunlight; but the fresh air is kept back from us. We speak only of the town. The mountains and the villages thereon, though not looked after well, are so situated as to be able to look after themselves in a manner.

But there is always the *mauvais cercle*—the constant current—ranging round some fixed point, or flowing onward. We miss them sometimes, but they find them (these two) at home among the snow, having climbed the mountains, and then they wander, maybe hand-in-hand (it seems so), down the valleys, and they are in our midst again.

They go as men go, these little, vicious rods made to scourge us, and they come again with the men that carry them to scourge us once more. Let them—they and all that are their bearers—abide each in his own place. We do not presume to say that segregation is a necessity; merely do we suggest that judicious supervision is in all cases advisable should we all be placed in a position to render each other's lives long and spent to best advantage.

Whether drawing their inferences from the instructions of physicians, or from book lore, or from what not, the people among whom we dwell have arrived at a sound judgment of the disease which it is best to avoid—with one exception. A wife is not driven from her husband on account of his suffering from typhoid fever. His friends and relations are sure to get under cover or get out of range; once the disease is diagnosed the word goes forth. Once the dread word "sill" (the meaning whereof is tuberculosis) is whispered, good-by to family and friends and wife together; and there are nursing and tending by strangers.

And then comes what one would look upon as the irony of it all! Diagnose a case of the disease that made Jenner justly famous, and you are as unto the man that used to make the silver shrines for Diana of the Ephesians—your craft is gone. They know that people have been, or ought to have been, vaccinated (the Turk adopted the method long before the European), and having a firm belief in the efficacy of the method as proved so many times among them, they wait and trust, and good-by to the medical attendant.

Prevention can hardly be taught to people like this. It seems it cannot be to people who, as the world goes, are more enlightened. In France, in one year, they say, nearly a quarter of a million fall from what we call preventable diseases. In London, a month's outbreak of influenza raised the average death rate to what might be called fabulous figures. It is a stale phrase, maybe, but the words are good—prevention is better than cure.

There is a great war raging in the Transvaal just now, and though the Boers and their allies have been trying their game of "fool's mate" against the English, the latter seem, at any rate, to have been playing a steady game against the intrigues of disease among their soldiers—disease is more destructive than war in the killing of men.

A MODEL DAIRY FARM.

To the Editor of the Medical Record.

Sir: I was very sorry not to have been able to be at the New York County Medical Society at its last meeting, for I very much wanted to hear and to take part in the discussion of the milk question. Having read the paper and the remarks of those who spoke on the subject I cannot refrain from supplementing them by giving a little of my observation regarding the handling of milk.

The reader of the paper is correct in assuming that the proper way to have clean milk is by care at the dairy farm.

It was once my pleasure and very great privilege to visit a properly conducted milk farm. The stable itself was situated on a hill. The building was well lighted and ventilated. One set of men, who had nothing else to do, kept the stable in a state of perfect and perpetual cleanliness. They wore a clean uniform of brown, and themselves were clean and healthy.

The udders of the cows were washed immediately before milking, each time, by a set of men who bore the same general description, save that they wore a uniform of blue. The cows were milked by a set of men who were if possible more cleanly than the others, and who wore uniforms of the purest white. Pails used for milking were provided by a man who did not go near the cows. These pails had been sterilized in a steam sterilizer for two hours before being used and then were locked, the milk entering through a strainer as it left the cow. Once in the pail it could not be taken out until the lid was unlocked. This duty was attended to by the man who cared for the pails at the entrance to the stable. He received the full pails from the milkers, unlocked them, put the milk in a forty-quart can that had also been sterilized, and when this can was full sent it off by an elevated wire to the milk-house, a quarter of a mile away—where it was received by a man in attendance, who himself was clean, and who put the milk into a large copper hopper, which had been within the last half-hour released from its steam bath, but was now surrounded by cold water in a sealed vat.

From this tank or hopper the milk ran down over a copper cooler, one side of which was in contact with iced water, and which had recently been steamed. From this cooler the milk flowed into another vat for bottling, which was accomplished without handling.

This last vat, like all the receptacles into which the milk goes, is regularly sterilized by steam, as are the bottles into which it finally goes. These bottles receive the most careful washing with a soda solution and then are steamed while upside down for two and one-half hours, and without handling of any kind receive the milk and then are sealed by hands that are aseptic.

There was nothing I could think of that was likely to contaminate the milk in any way, and it was thoroughly aerated and was cooled in a very few moments after leaving the cow, and put on ice.

This milk will keep for a very long time if on ice. It has been sent to Europe and back remaining perfectly sweet and good. How long it will keep when thus treated no one knows; but I think I had some once two months old, perfectly sweet and good. Just as much care is used in the care, feeding, and selection of cows as in the handling of the milk.

Four physicians and two veterinarians are employed to examine the cows, and look after and certify regularly to the healthfulness of both the cows and the milk.

Surely this is near the ideal condition; and since it has been very profitable to this man it undoubtedly would be so to others; and I wish this description of a successful and thoroughly satisfactory milk farm could have gone with the discussion of the subject at the County Medical Society.

Wickes Washburn, M.D.

February 10, 1900.

ODOR RECORDS.

To the Editor of the Medical Record.

Sir: In your London Letter of December 29, 1899, there is a remark concerning which I have thought much. It says: "But in most zymotic diseases we are still searching for clear, easily applied diagnostic tests." A short time ago I had a case of obscure rubeola accompanied with typhoid symptoms. The eruption did not indicate the disease and was very slight. Now the thought occurred, if one could have a sensitive plate which would record a photograph of either the odor or emanation of the various eruptive fevers it would be of great value in either an early or difficult diagnosis. Say, to have the patient breathe upon the plate and to be able to make a photograph of various emanations from different fevers. For those who have the time the above suggestions might lead to interesting and useful experimentation. Our knowledge of odors is quite limited, and I would like to offer the above as a possible way to increase such knowledge.

W. G. Cotton, M.D.

East Bethlehem, Pa.

THE MEDICAL ASPECTS OF THE WAR IN SOUTH AFRICA.

(From our Special Correspondent.)

The Numbers of the British Troops.—The beginning of the third week in February brings no successes to British arms, and the story of each battle, whether a genuine engagement or only a "reconnoissance in force," is the same. The Boers, having taken ample advantage of the opportunities given them while numbers were on their side, and having used well their knowledge of the country and their peculiar aptitude for a certain class of warfare, have taken up impregnable situations between the British forces and the towns to be relieved. Numbers, overwhelming numbers, of soldiers will have to be employed by the British in the attacks, so that, like a sea, they may flow round the Boer positions; otherwise success is hardly to be expected for them. This is now realized by the British government. Only a month ago I gave you the exact figures of the British troops as 70,000 all told, the medical officers numbering 160. By the beginning of February the total of British troops in South Africa amounted to 179,000, made up as follows: Regular army, 128,000; navy, 1,000; militia, 9,000; yeomanry, 5,000; volunteers, 10,000; and colonials, 26,000. Of the colonial troops, 20,000 were raised in South Africa, and 6,000 have been sent from Canada, Australia, and other dependencies. The medical staff has been augmented in proportion, and there are now in South Africa, or there will be in the course of a few days, 368 officers of the Royal Army Medical Corps and 133 civil surgeons. The proportion of medical officers to the total number of troops is worth noting. As the war has been characterized by heavy fighting, and as the British medical arrangements have been on all sides considered adequate, it may be held that this proportion is as high as is necessary.

The Attempts to Relieve Ladysmith have so far been unfortunate. The second attempt, which resulted in the capture and subsequent abandonment of Spion Kop, was attended by considerable loss of life, but the third, which was rather a reconnoissance than a deliberate forward movement, brought no casualties in its train. The capture of Spion Kop cost the British 34 killed and 61 wounded officers, 217 killed and 1,115 wounded men, making 1,744 in all. (I include in these figures the casualties attending the accompanying or preceding movements at Venterspruit and Potgieter's Drift.) It will be seen that the death rate among the officers was very high, testifying to the good marksmanship of the Boers. If ten per cent. of the total of 1,176 wounded die—which is rather above than below the average at present shown by medical statistics of the war—the total deaths will amount to 368, so that the advance was a costly one. Two-thirds of the wounded will, however, probably be fit to serve again in three weeks' time. This, again, is based upon medical statistics. From which figures it will be seen that while modern warfare calls for many men because of the heavy slaughter that may occur at one point, it also allows the same men to be used many times, because the wounds from the Lee-Metford and Mauser rifles tend to heal so rapidly. The third attempt to relieve Ladysmith was attended by no fighting. Its failure places the beleaguered city in a sad plight, but the garrison is not only in good spirits, but in far better health than it was, the attacks of typhoid fever being much less numerous.

The St. John Ambulance Association, which is entrusted by the Central British Red Cross Committee with the reception and forwarding of material for the sick and wounded to the seat of war, has sent to South Africa 5,855 suits of pajamas, 9,293 shirts, 23,603 handkerchiefs, 2,319 pillows, 6,409 pairs of socks and stockings, 6,210 pairs of slippers and shoes, 1,471 knitted caps, 1,080 knitted jackets or cardigan vests, 4,735 knitted mufflers, and 694 cushions—not to exhaust the list. These things have been sent at the instance of medical officers and other competent judges at the front—Colonel Young, the secretary of the Red Cross committee, for example—and the choice of articles shows well where the kit of the English soldier, which I have already detailed to you, is deficient. Light, warm, durable things will be the costume of the future soldier all over the world, and smart regimentals will become as obsolete as the greaves, visors, and breastplates of the Crusaders. The opposing forces on the veldts are fortunate in the weather which they are experiencing, but the drenching showers and heavy dews, no less than the hot sunshine of midday during what is the South African summer, taken together mean that the clothing of the soldiers must be woollen. As proving the great variations of temperature in the summer months in Cape Colony, the most recently published observations of the government meteorologist show that in January, 1898, the maximum temperature at Graaf Reinet was 108° F. and the minimum for the same month was 40° F. At Kenilworth, just outside Kimberley, where the next British advance in force will be made, the maximum black bulb in the sun was 159.8° F., the highest shade temperature being 94.7° F.; the minimum black bulb on the grass was 39.1° F., the lowest shade temperature being 44° F. For such a country wool is the only wear.

Military Medical Attaches.—Two German military attachés, Stabsarzt Dr. Krumacher and Stabsarzt Dr. Schmidt, have been up to the front at Modder River, and on their return to Cape Town expressed their satisfaction with all that they saw. As the casualties with Lord Methuen's column were extraordinarily heavy at Magersfontein, the fact that critics of another nation were complimentary has been received by the Royal Army Medical Corps with particular pleasure, for it proves that the corps is as good in an emergency as it is with lots of time before it and lots of money to spend. These attachés from the German army are the only foreign military medical men who have yet made their appearance at the seat of war. Sir William MacCormac, who has seen other campaigns in a volunteer capacity, considers that the move is a very wise one on the part of Germany. The care of the sick and wounded is becoming much better understood among civilized nations, and if accredited representatives of military surgery from other countries fall generally into the way of accompanying belligerent forces the result can only be an increase of knowledge that will be of the highest service to humanity.

The Hospital Ship "Maine."—This hospital ship, the splendid gift of American ladies to the British government, had in the second week in February one hundred and forty patients on board her, half of whom were wounded during the attack on Spion Kop, the other seventy including sixteen cases of dysentery, fourteen of rheumatism, four of ague, and three of typhoid fever. The *Maine* lies at Durban.

The Utility of Hospital Ships has been called in question by some of the medical men serving in South Africa, but it is not their employment at Durban or Capetown to which exception is taken, but their use as transports. There are many large transports available from Capetown to Southampton, and those in charge of the base hospitals say that the accommodations offered by them to the sick and wounded is ample, inasmuch as no one is sent back until his plight has ceased to be urgent. This being so, the necessity of using to take the sick and wounded to England slow, small ships, expensively equipped with operating-theatres and *x*-ray chambers, is certainly not very obvious. But to bring the sick and wounded, while still suffering acutely, from Durban round to the base hospitals near Wynberg these ships are of the most splendid utility. They have saved the lives of many, and have eased the pains incident upon travelling of thousands of poor fellows. In addition to these hospital ships which I have already mentioned to you, a new one, the *Nubia*, has just been equipped. Like the *Lismore Castle*, she has been transformed from the ordinary passenger steamer of the Peninsular and Oriental Steam Navigation Company to a hospital ship by the rapid work of the plumbers, carpenters, and painters of Durban. She makes the sixth hospital ship.

A Scottish Hospital in South Africa.—Scotland, in emulation of Ireland, is sending out a hospital to the seat of war, but, like Lord Iveagh's Irish Hospital, there will be no national or regimental distinctions made in the selection of patients to be relieved.

The American Field Hospital.—Mr. Van Alen, an American gentleman, has presented the English government with a complete hospital of twenty-five beds. This is one of the most princely contributions yet received by the government. Dr. E. G. Powell is to be medical officer, and the secretary-superintendent is Mr. Murray Guthrie, the newly elected member of Parliament for an East London constituency.

STATIC INDUCED CURRENT AND DR. MORTON.

To the Editor of the Medical Record.

Sir: The witticisms and personalities indulged in by Dr. Morton in his reply, not to my "gratuitous attacks," but to my just accusations, have nothing to do with the case in hand; nor do they alter the facts. He says that he is still waiting to hear from me, and that "practically no one disputes his humble claims." Has he so soon forgotten Professor Pupin's vigorous handling of some of his extraordinary claims? Let me refer him and any others interested to his own article and Professor Pupin's reply in *Electricity*, February 19, 1896.

And now, in the first place, although not specially germane to the central idea of the subject of discussion, let me call Dr. Morton's attention to the fact that Reiss' singing telephone was also a microphone with two platinum points in contact by gravity. There was no adjustment screw and none was needed. Therefore the turn of one-millionth of an inch in order to transform it into a speaking telephone is a dream of his own. If Reiss had had carbon instead of platinum, he would have had the telephone of the present day.

The accompanying illustration and description from Tibbett's "Handbook of Medical Electricity" (London, 1873) shows clearly enough with what accuracy Dr. Morton has reproduced the ideas of others as his own. The author of the work ends his description of the machine by saying: "The two exciters *K* and *J*, representing the charge of the outer and inner coating of the jar, can discharge it through any muscle. The intensity of the charge is regulated by the distance apart of the balls *E′*, *J*."

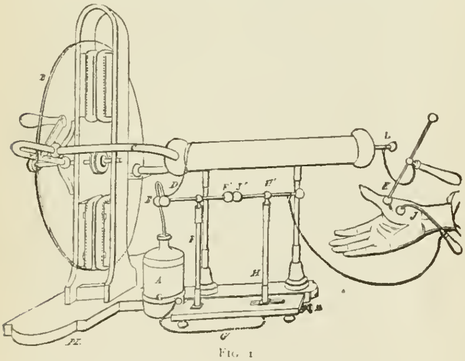

Fig. 1

Dr. Morton has simply copied in its essential details this illustration, or some similar one, from the earlier French or English issues—Mauduyt, Imison, Adams, or Cavallo—and given to the current that these old fellows knew of and used the name "static induced." That long before his time this current not only "could be," but was utilized, is evidenced by the second illustration.

Fig. 2, taken from Mauduyt, 1784, represents an application to a very sensitive part by what they called shocks (they called almost everything shocks), but shocks regulated by so fine a graduation of the spark gap as to merge them into a veritable current. These men of a former time had everything but the name.

Dr. Morton says truly, that the old writers describe their administration and discoveries with the minutest detail, and no one knows better than he how often allusions can be found to the electric manifestation called the static induced current. I quote from one of them, "Cavallo on Electricity," vol. ii., page 123 (London, 1786). After describing an arrangement substantially the same as the one above given, he says: "Thus any number of shocks precisely of the same strength may be given without altering any part of the apparatus . . . and when the strength of the shock is required to be diminished or increased, it is only necessary to diminish or augment the distance between the balls *B*, *C*." These balls correspond to the balls *E′*, *J*, of our first illustration. In a work on electricity by Adams, published in London, 1792, page 514, he describes his seventh method of application thus: "By a sensation between a shock and the spark which does not communicate that disagreeable feeling attending the common shock. . . . The effect of this species of shock, *if it may be called one*, [italics mine] is to produce a great vibration in the muscular fibre without inducing the pungent sensation which the shock effects." These are nothing more nor less, could be nothing more nor less, than what Dr. Morton claims as his wonderful discovery of the static induced current and physiological tetanus. In Cavallo, again, page 157, we find the statement that small shocks, *i.e.*, one-twentieth of an inch, may be sent through the pelvis. With this slight separation the result could be nothing else than the static induced current, and it is useless for Dr. Morton to flippantly say they "could but they didn't." But why multiply examples which are so readily verified by reference to the original sources that I have mentioned?

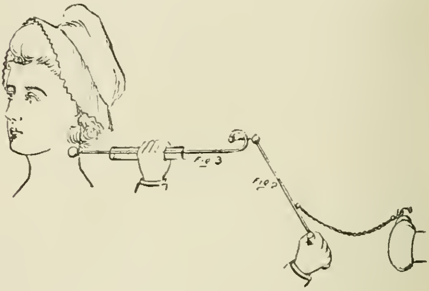

Fig. 2

As for Dr. Morton's article on "Electrostatic Currents and the Cure of Locomotor Ataxia," etc., it seems to me that the title alone is enough to condemn it.

Speaking from an experience quite equal to his own, possibly, in the treatment of gross organic diseases by the very same as well as by other electrical methods, I know well enough how unsubstantial are the claims he makes and evidently wishes to be inferred. So far as I am concerned, this discussion is closed. Each one who has been sufficiently interested to read what has been written, and will consult these old works, will form his own opinion as to the measure of Dr. Morton's originality and the value of his therapeutic claims. I began the discussion not because I do not thoroughly believe in the value of electricity as a therapeutic agent, but because I believe in it so much that I regret to see it discredited in the minds of the conservative, thoughtful members of the profession, by asking of it so much more than it is capable of doing.

PROGRESS AND DRIFT IN PATHOLOGY.[1]

BY T. MITCHELL PRUDDEN, M.D., LL.D.,

NEW YORK.

THE closing years of the century have inspired so many summaries of progress and such a diligent casting of horoscopes that one should not lightly indulge in another inventory or invite to new outlooks in medicine. But there are, it seems to me, some border-lands between the purlieus of the practitioner and of the pathologist which we may profitably survey. I have in mind not so much a summary of facts as a glance at tendencies, an estimate or realization of the point of view to which we have more or less purposefully won our way, or toward which we mayhap have only drifted, during the past two decades.

It is, I think, unfortunate that the practitioner often forgets that he is still a pathologist; that the clinical studies which largely command his time and mental resources are studies in pathological physiology. That which we are wont to call pathology is really those phases of the etiology and morphology of disease which can be more easily, and often more completely, studied at the autopsy table and in the laboratory than at the bedside. Using the word in this sense, the pathology of twenty-five years or so ago was in this country pursued almost exclusively by practitioners of medicine, and it was avowedly an adjunct of medical and surgical practice. The most distinctive function of the physician-pathologist was the making of autopsies and the naming of tumors. These things he did, either to increase his knowledge, or for the skill and experience which were useful stepping-stones to practice; or because he wished the material for demonstration to students; or because this work held out the promise of interesting themes for study and a paper.

Finally there appeared upon the horizon in this country a few anomalous individuals who cherished the notion that the science of disease, even in its etiological and morphological aspects alone, was broad and deep enough to command the exclusive attention of its devotees.

Twenty years ago, the most obvious aim of the special pathologist, apart from his material service to the practitioner along the old lines, was to discover some new lesion or to give greater precision to the morphology of an old one; to gather statistics; to exploit organs of exaggerated size; and in general to celebrate the monstrous and the strange. Nomenclature and classification were his cherished fetiches. His battles royal raged about the origin of pus, the nature of cell stimulation, the relative importance of the various phenomena of inflammation, and the possibility of the successful transplantation of tumors. The experimental method was in vogue, the doctrines of the cellular pathology were dominant, and there was year by year a steady gain in facts.

It was the facts, in truth, which were troublesome from their rapid and prodigious accumulation. For the correlation of the facts was at that time difficult or in many cases impossible. So description and cataloguing, not explanation, was the business of the hour. The blind devotion to minute objective description of lesions in man of which no one knew the origin, the significance, or the relationship, was as praiseworthy as it was pathetic.

I would not underrate the achievements of those years in the seventies, nor the sound scientific spirit which underlay them. But it was in truth e'en standing water between the cellular pathology of Virchow and his early followers, and the cellular pathology which was to be reincarnate by correlation with and illumination by other phases of science, from which medicine had long held aloof; and by a fresh stimulus to research through new light on the infectious diseases.

The conception of the cell was no longer as at first that of a membranous bag containing active substance, but of a lump of protoplasm. The intimate structure of the cell had no particular significance, except that one had learned to recognize a granular appearance in the body, a stainable object in the interior called the nucleus, which in its turn often revealed one or more darker spots within. The cell did wonderful things indeed, and, as the doctrine of the conservation of force became current, was looked upon by those who had enjoyed some training in physics and chemistry as a centre of physical and chemical activities in which occurred those transformations of energy required in the dynamics of life. So prominent in those days were the chemical aspects of the cell, that the manifestations of life, assimilation, growth, and reproduction were looked upon, and justly too, with the knowledge then at command, as properties of the not very complex chemical organic compound, protoplasm. And speculations involving a chemical theory of life seemed not so very unreasonable. The cell studies in pathology of those days, a quarter of a century ago, were largely limited to changes in the shape, size, and position of the cell; to its degenerations, and to the cruder destructive processes to which it is subject.

But the studies of the past few years, especially upon the lower and simpler cell forms, have wrought a complete revolution in our conception of these elementary organisms. The cell is no longer a lump of living matter of rather simple chemical composition which transforms energy, and whose intimate structure we need not worry about. It is a most complex machine whose varied structural features are of the utmost significance. The nucleus harbors the special structures closely involved in reproduction and heredity, and is deeply concerned in the processes of cell nutrition. The chemical substances of which the cell is composed are numerous, and the physical comparison of protoplasm with a lump of jelly is no longer adequate. Already, while we as yet are only upon the threshold of this new cytology, cell structure demands an extended nomenclature of its own, and whole treatises are written upon the performances of its varied mechanisms. Into this field pathology has barely entered, halting still behind the students of normal and lowly cells.

---

[1] Read before the Practitioners' Society of New York, February 2, 1900.

Moreover, we are admonished by these brilliant discoveries that the secrets of cell structure and cell function are hardly to be won by the study of higher forms alone. In our extremely differentiated and intimately co-ordinated cells, many features fundamentally simple are veiled or modified; so that we can understand them only when we interpret them in the light of less advanced forms.

Thus it has come to pass that while the pathologist of a couple of decades ago found his morphological studies of the cell ended when he had made a few crude observations on its size and shape and texture, the pathologist of to-day counts all these as but glimpses on the threshold of a domain in which his problems demand the most accurate technique; the most minute observation; a recognition of the dominion in his own fields of universal physical and chemical laws, of the doctrine of organic evolution, and of the potency in single cells and in cell communities of hereditary traits and tendencies. We can, it is true, with the cruder superficial observations on the form and grouping and texture of cells, still make the morphological observations which the exigencies of practical diagnosis require, but this is done in the consciousness always that clews to unknown phases of disease are eluding our grasp, and that it is not thus that the more subtle maladies are to be comprehended.

Curiously enough, it is in the nervous system, which so long occupied a mysterious little pathological bailiwick of its own, that the new phases of cell study in pathology have been most diligently pursued. Not yet, it is true, in such fashion and to such extent as to have secured unanimity of interpretation, but sufficiently to suggest high promise, here and elsewhere, for the future.

Let us now turn to another phase of progress in pathology and briefly consider its promise, its drift, and its disappointments. We can all recall the vague conception of the causes and nature of the infectious diseases with which most of us entered upon our active careers in medicine. The lesions which we found after death were often indefinite and unsatisfactory, and preventive measures, dealing as they did with the unknown, were for the most part halting and futile. We had grown weary of the personification of disease, of the conception, and the treatment too, of morbid processes as if they were things, and of the persistence, in nomenclature at least, of ideas about the causes of disease which belonged in the era of barbarism, superstition, and personal devils. While we knew that disease was really a process and not a thing, we got, or thought we did, some help by calling certain of the infectious diseases "specific." But this comfort was meagre and short-lived.

The word "specific," as we all have frequent occasion to deplore, is used in varied senses and often with no sense at all. To some, it is that which pertains to a species, as of animals or plants. To others, it connotes a disreputable trio of venereal diseases. As applied to cells and other structures of the body, it signifies something typical and characteristic in the structure, the metabolism, or the performance—as a specific secretion of a gland. It is applied to the action of poisons, which vary among themselves in their effects upon the same structure, and which vary as individuals in their action upon different structures. On the other hand, the term "specific" came to be applied long ago to certain infectious diseases which were so peculiar, so characteristic in their clinical manifestations that an enumeration of their symptoms served for their identification, as species were identified among plants and animals. Thus the infectious diseases became personified, became species, things, entities, and their specificity was expressed in the description of symptoms. But after a while it was more clearly seen that disease as a process involved the action of the living body cells on the one hand and some then unknown inciting factor on the other. Then it dawned upon the medical world that, after all, the actually characteristic thing, the really "specific," was not to be sought in the symptomatic manifestation of disease, but in the underlying agencies which determined its occurrence. And so the light failed in which we had tried to find comfort, and we realized that to call the infectious diseases specific didn't really make them any more comprehensible.

All at once the mystery seemed to be swept away. In the place of vague speculation on the causes of the infectious diseases, we had definite, tangible, visible, living things to deal with, in some cases certainly and by fair inference in all. The term "specific infectious disease" promised at least to mean something precise, and the most "specific," characteristic, essential, determinative thing about it appeared to be the particular germ species which, as it seemed, alone and always caused it.

It is of great significance that while the most striking contribution of Koch to the science of that day was the formulation of a very simple technical procedure in bacterial culture and study, he went beyond that and threw the whole weight of a strong and convincing personality and the commanding power of an excellent teacher into the enforcement of so positive and detailed a conception of the nature of the infectious diseases, of the characters of the things which, as he assumed, "caused" them, and the practical measures necessary for their control, that he fairly forced upon the medical world a new school of thought and practice.

Everything conspired in these days to fix the attention of the medical world so sharply upon the microbe that the man side of the matter was largely ignored, and Virchow, with the cell lore which he had gathered or inspired, sat glowering and protesting in the shadow as the procession swept jauntily past. No young pathologist was so ill provided with utensils and none so busy that he did not hasten to lay some new microbe at the newly risen shrine. The older pathologists were for the most part too dazed and confused by the new shibboleths and the clamor to join either in protest or acclaim, but held aloof babbling softly of cells and stimuli and tumors and heredities. The average practitioner was mildly interested, judiciously incredulous, took it all apparently as a part of the passing show, and went on doing good and earning his living.

The poor old fellows struggling along in the dark before the eighties spent many nights in vigil and many days in toil in the vain task of deciding whether phthisis was always tuberculous. The pitiful morphologists had struggled through many a claim and many a renunciation without clear light upon the relationship of the different pneumonias. Diphtheria or croup had stimulated many a hot encounter. But now that you could put your finger upon the "specific cause" so easily and so surely, the road seemed plain. If the tubercle bacillus were there, the disease was tuberculosis. It needed no jury if the pneumococcus were lurking in the lungs. Diphtheria or angina?—send a swab to the laboratory.

But let us see what the words "cause" and "disease" really mean which in these days under cover of the microbe we had begun to juggle with so blithely.

The devotees to medicine are so largely absorbed in the practical aims which are at once their glory and their undoing, that no one seemed to realize at first that in using the word "cause" to express the relationship between these newly exploited germs and the diseases with which they had been found to be so closely associated, they were plunging headlong into a mistiness of conception in which the human mind had long floundered. For it was not until the physicists had taken the matter in hand that clearness of expression about causes was secured in dealing with forms of energy. Now it seems to me that without risking an excursion among the pitfalls of metaphysics, we might secure a practical advantage if we were to cease to speak of microbes—at least without a mental reservation—as the cause of disease. For to do so is fundamentally or in a dynamic sense as inexact as to speak of the spark which starts the train of chemical decomposition in gunpowder as the cause of the explosion. The microbes may be, indeed they are, absolutely essential factors in certain diseases without having that quantitative relationship to the effect which, in the physical sense, true causes must always bear.

Hueppe has rendered a great service to medical science by calling attention again and again to this erroneous conception, and by reminding us that in the end we must recognize the doctrines which the physicists have laid down in studying the forms of energy, which in all their subtleties and intricacies apply just as absolutely to the manifestations of energy in the human body as in the domain of inorganic nature.

The fire which burns in my grate is not caused, I think, by the lighted match, but by the molecular potencies in coal and air which the match has set astir. Nor is the play of forces which it has evoked a thing. The coal, the air, the ashes—these are things, these are entities; but the molecular activities, the transformations of potential into actual energy, the burning—these are not things; they are processes. And so it is with disease; it is a process, not a thing. Indigestion is no more a thing than is digestion; both are processes; both are, at bottom, transformations of energy. Their differences are due to differences in the conditions under which the forces are brought into play.

The normal processes are what they are because of the conditions under which the cells have been slowly evolved and are at the moment placed. The abnormal processes involve no new forces, but are what they are because the manifestations of energy of the normal state are modified by new conditions. This transformation of energy occurs, indeed, in both cases through a definite mechanism, and this mechanism may suffer modification under changed conditions so that we may have lesions of disease. But the lesion is no more the disease than the ash or the coal or the air is the burning of the fire.

The cause of physiological performances is the potential energy, the capacity for doing work which the organism possesses, drawn from the universal storehouse whose total stock never wanes. The true causes of disease are the same dynamic forces acting under modified conditions. Under these modified conditions, the potential energy of the living organism may be set free in a variety of ways. But diverse as these ways may be, they involve only the liberation and not in any marked degree the supply of energy. They belong among what the physicists are wont to call "liberating impulses," or sometimes "secondary causes," and are the analogues of the spark which with a minimal amount of impulse makes possible the transformation of potential into kinetic or actual energy. I think, therefore, that it would be wise if we were to cherish the conception of the microbes which are regularly involved in the infectious diseases, not as causes, but as inciting factors.

That which the physicist calls a secondary cause is designated by the physiologist as a stimulus. Similarly, we might perhaps wisely call these liberating impulses the stimuli or excitants of disease.

Of course the word "cause" is commonly and not improperly used in a less limited sense than that here urged, and this ordinarily does no harm. But in this case the unrestricted use of the word does, as it seems to me, do harm, because it constantly diverts our attention from a fundamental to a subsidiary though not unimportant thing.

The manifestations of the infectious diseases are expressions of processes of the body cells and not of the micro-organisms, which only afford one of the necessary conditions. Of course you cannot have tuberculosis, for example, without the tubercle bacillus. Nor, on the other hand, will the tubercle bacillus incite tuberculosis in an oak plank. If the tubercle itself were essentially a heap of tubercle bacilli; if the various and significant subsidiary phases of tuberculosis, the fever, the malnutrition, etc., were expressions of perverted life processes of the bacillus and not of the man, then I grant that one might be justified in considering the tubercle bacillus as the cause of tuberculosis, and man simply as an indispensable condition.

The requirements of sanitary science and preventive medicine may perhaps be more easily met by the use of the word "cause" in treating of the microbes as inciting factors in infectious diseases. But our own conceptions must be clear as to what are real and what only apparent causes, if we are to avoid in the future the pitfalls which have marked the advance of the medical and other sciences.

Such considerations as these are, as it seems to me, not unimportant. The science of medicine has suffered greatly in the past, and still suffers, from the tendency, almost universal among its devotees, to consider the human body as a thing by itself; an object which can be studied and treated without regard to the close relationship in every cell and fibre with forms of life which are its prototypes; and without regard to the identity of the forces which sway alike the molecules of the cell and the molecules of the air, the drop, or the crystal. It may be that in such considerations we gain no hint which will reveal a clearer symptom, a safer method, or a better pill. And if the horizon be for any limited, by necessity or by choice, to these outlooks, then he may slumber while we prate of causes and entities and dynamics. But if we are going to talk of causes, let us know, if we can, what the word signifies. If we mean processes, let us not say things.

The trouble with the point of view which was so early formulated and so successfully urged by Koch was that what he conceived to be the causes of the infectious diseases are really only the inciting factors. The result was that the lines of study led away from the body to the germ. The beautiful simplicity, the precision of conception, the technical ease, with which discoveries were made were all due to the fact that we were ignoring the real complexities of the situation, entering with an easy enthusiasm upon new fields which of right belonged to the botanist. So long as the study was one of cultivation, description, and species-making, the pursuit of bacteriology seemed a succession of simple tasks. But complexities soon began to reveal themselves.

Koch was especially insistent upon the definiteness and permanence of specific forms, as indeed it was necessary to be, if the so-called causative relationship was to be maintained between specific bacteria and specific diseases. But the matter has proven not to be so simple after all. For although there is, so far as I know, no evidence that one well-defined species ever changes into another, there is a certain lability, especially in the physiological characters of many bacteria under variations in environment, which renders species-making and classification in these organisms a parlous job.

When the establishment of bacterial species was fairly under way, it became evident that although we had the advantage of other species-makers in higher plants and animals, in that our subjects went through their life cycles very rapidly, so that we could gather the available facts in a few days, or at most weeks, we were yet seriously embarrassed because we had to depend for specific characteristics largely upon physiological data, the available morphological differences being very few and limited in scope.

Let me illustrate what I mean by lability in the physiological characters upon which species determination among the bacteria largely depends. At an early day the bacteria were divided into three great classes: the zymogenic or fermentation-inciting, the chromogenic or pigment-forming, and the pathogenic or disease-producing. These characters were believed to be sufficiently precise to justify this great group division. But it soon appeared that each of these activities is variable. Chromogenes can grow without their color. Zymogenes may be swayed by artificial means up and down the scale of activities. Pathogenes may be rendered innocuous. But more than this, it was presently discovered that chromogenes and zymogenes might be pathogenic; that zymogenes might produce color and chromogenes cause fermentation. Form, too, is subject to considerable change, and spore producers may be made asporogenous. Those germs which naturally require oxygen for growth may be made to do without it, while anaerobics may have an aerobic existence forced upon them.

As the stability of these characters grew unsatisfactory as a basis of classification, it became more clear that the alterations in capacity of these organisms were due to changes in the conditions of life, such as temperature, light, food supply, the presence of deleterious substance at the seat of growth, etc. Thus the development of qualities and capacities which at first were deemed specific to the germ were found to depend quite as much upon external as upon internal conditions. This was an old story in science, but it was new in bacteriology. We have, in fact, owing to the wide range of variation which some bacteria display under different conditions in their environment, been finally compelled to establish certain groups which seem to belong to what we are pleased to call the same genus, but which are so variable in form and physiological manifestation that we are unwilling longer to incur the peril which belongs to the attachment of a specific name. When one hears nowadays, therefore, of the coli group, or the diphtheria group, or the tubercle-bacillus group of bacteria, he should realize that this indicates just a refuge by the way in which bacteriologists have sought shelter and safety from the fury and risk of species-making, until new light dawns.

These complexities in bacteriology when applied to the conception of the relationship of micro-organisms to disease were further deepened by the realization that not all animals are affected alike by the so-called pathogenic germs; a fact which now needs no illustration.

The notion of bacteria as disease entities was further shaken by the revelation that the same germ may incite more than one disease. Suppuration may be induced by the typhoid bacillus, the tubercle bacillus, the pneumococcus, and the anthrax bacillus, as well as by those germs which were at first called *par excellence* pyogenic. The pneumococcus is the inciting factor in only one phase of pneumonia, and it may be responsible for meningitis, endocarditis, and so on. In a word, it soon became clear that the action of a given germ in the living body depends only in part upon its intrinsic capacities—which in themselves are very variable—but also and in marked degree upon the capacities, also variable, which exist at the moment in the body cells among which the lot of the germ is cast.

Thus the conception of bacteria as the "specific entities" of disease lost much of its keenness; the body cells came quickly to the front, and Virchow smiled again.

We now realize that disease is, as Hueppe has happily expressed it, like an endless chain, from which if any link be missing the closing of the chain is impossible and the disease cannot occur.

When once attention was turned from the microbe aspect to the cell aspect of infectious disease, facts of the utmost importance began to accumulate about natural or artificial predisposition, immunity, acquired tolerance to poisons, etc., to which the scope of this paper permits me only briefly to refer.

The tendency to a one-sided interpretation of facts, which, as I have tried to show, characterized our earlier knowledge of bacteria as inciters of disease, was again manifested when attention was directed to the effects of poisons, bacterial and other, in the body. And here, too, a group of investigators came presently to think that it was the toxic agents, in which the "specific essence," the "primary cause," of most of the infectious and many other diseases was to be found. And it really seemed at one time, as Martius has pointed out, as if, apart from traumatic and certain strictly mechanical disturbances, pathology were in a fair way of becoming merged in toxicology. Auto-intoxication loomed big upon the horizon, not simply as a most significant factor in pathogenesis, as it unquestionably is, but as the very essence of disease. All organic diseases which depend upon destruction of the parenchyma, most proven or alleged microbic diseases, and many less readily characterized diseases such as leukæmia, were to be considered as fundamentally auto-intoxications. And these diseases were to be classified on toxicological principles. The considerations which I have urged against partial views in speaking of the bacteria are pertinent here also, and have already fostered wiser and saner conceptions.

I have touched in a somewhat critical vein upon some early phases of drift in bacteriology, because since we are yet only upon the threshold of knowledge in this domain it is of great importance to have a clear vision of our aims, and because a good deal of unnecessary complexity in problems of the hour is still due to narrow views of the relationship of micro-organisms to disease.

I wish that it were practicable for me to devote a few moments to a survey of our drift and progress in fields which concern immunity. For I think that this subject has been unnecessarily cumbered with conjecture and hypothesis not based upon a clear conception of the actual relationship between variable inciting factors on the one hand, and the variable mechanisms on the other, through which the dynamics of life are manifested. So much has been written about immunity, and such multitudes of half-apprehended and wholly inco-ordinated facts are lugged into the discussion, that, in reading on this theme, one is reminded of a saying of Montaigne, that "there is more ado to interpret interpretations than to interpret the things themselves."

We are apt to forget, in our thought of immunity and tolerance and health and disease, that the life of the cells of the body, like the life of the microbes, is a continuous adjustment between the properties of the organism and those of its environment; that the nice balance which we name health may be swayed now this way and now that by a thousand subtle agencies from within the body and from without; that the body cells as well as the bacteria are organisms capable of considerable variation both in form and function when the conditions of their existence change.

When we talk of immunity and antitoxins, we are apt to forget that natural or acquired cell tolerance to poisons may be, and in many cases certainly is, a matter of cell education. So that, as Hueppe has pointed out, we do not need to assume, in the presence of an acquired tolerance to alcohol or morphine or arsenic, the presence in the body of a "specific" anti-alcoholin or anti-morphine or anti-arsenicin. There is no doubt a condition, capable of being artificially induced, which we may properly call, if we utter some *sotto voce* exorcism as we name the words, "specific immunity." But the balance of cell metabolism is so subtle, and the introduction of new substances into the body can modify in such marked degree the responses of the cells to various poisons, bacterial or other, that the phrase "specific immunity" should not be lightly conjured with. The pathologist has never realized so keenly as he does to-day how dependent he is upon the ministrations of the chemist not only for his conceptions of the ways in which the life energies are stored and poised, but also as he faces those protean aspects of disturbed metabolism which lie at the heart of so many of his problems.

The substantial gains in all these years of research into the nature and mode of diagnosis and treatment of the infectious diseases—I could easily contrive a wearisome hour of inventory—it is not my purpose to review. But I cannot leave this phase of my subject without a protest against a too hasty inference of doubt or of failure because the new interpretation of facts in these rapidly growing fields of science may seem for a moment, now and then, to denote a backward drift.

The technical difficulties which we have encountered and the really only superficial changes in bacterial nomenclature which the hour demands may well be puzzling and discouraging to the harried practitioner who is forced to read as he runs. Bacillus coli communis may not slip so trippingly as at first from the tongue. The bacteriologist may not enter so jauntily as was his wont upon the capture of a stray typhoid germ in the water of a suspected well. The swab from the throat may not always unlock, so surely as was hoped, the secrets of diphtheria. We may, as seems likely at the moment, even be compelled to call the tubercle germ not a bacillus but a fungus. But these changes to which I have referred do not, in fact, involve the relinquishment of one jot of the solid practical vantage-ground which the earlier studies won.

In the light of our new knowledge of tuberculosis, attention was at first directed almost wholly to the tubercle bacillus, while the body aspects were largely ignored. There had been substantial agreement that in the prevention of this disease the destruction of the sputum and an intelligent cleanliness were of supreme importance. Now that we are looking to the man side and realize that predisposition is also of great importance, we are beginning to hear deprecation of serious efforts to destroy the infectious agent, and are counselled to lay the greatest stress upon improving the health and thus, as it is assumed, strengthening the resistance capacities of the individual. This it is entirely proper and wise to do. But we should not forget that we do not as yet know at all definitely what the factors are which make one predisposed to tuberculosis and another not. So that we are compelled to fall back upon rather vague suggestions. On the other hand, those measures which have approved themselves, in the care of the sputum, and the sequestration, when it is practicable, of the sick, are positive and proven and should not be lightly relinquished.

I believe that the conclusion to which the surgeons have come, in regard to the relative or even absolute harmlessness of aerial micro-organisms which may enter fresh wounds at operations, are sustained both by practice and by the knowledge of the varying virulence of germs which has been gained since surgery emerged from the illuminating incubus of Listerism. But I think that the conclusion affords no justification for a lack of attention on the part of practising physicians to the risks which their patients who are seriously ill are subject from secondary infection, due to the inspiration of dusty air. For the sick man who is breathing germ-laden air is largely deprived of those natural safeguards against infection which at the portal of entry in the surgical case are usually in full activity. The exposure of the sick man is not momentary, but continuous. The nasal filter is often thrown out of function by mouth breathing; the buccal secretions are scanty or altered; the cilia of the air passage share in the disabilities of the body at large, so that access is relatively easy to the recesses of the lungs; while finally the internal protective agencies are often feeble or ineffective. I have not time to pursue this subject, but I think that the methods of cleaning in hospital wards and in sick-rooms might well claim a more careful consideration than is common from practitioners of medicine.

I now turn, in illustration of new outlooks, to the subject of inflammation. When most of us were serving our novitiate in pathology, the study of inflammation was largely limited to a bare description of visible phenomena and a cataloguing and classification of lesions. Like other diseases, inflammation was regarded with more or less complacency as an entity, a thing. We were engaged in studying the ways in which the blood cells, especially the leucocytes, got out of the blood-vessels in the exudative phases of inflammation; and the more inquisitive among us were much exercised to find out whether it was the emigrated leucocytes or the fixed connective-tissue cells which were most concerned in the formation of new tissues. So earnest were the advocates of each of these views that the social amenities sometimes suffered. Thus it was my hap to be banished from Stricker's laboratory in Vienna when it became known to that champion of the connective-tissue cell that I had been under the baleful influence of Cohnheim and Arnold.

This question of the origin of new connective tissue, the minute alterations in the walls of the blood-vessels which permitted emigration and diapedesis, and whether the leucocytes crawled out or were squeezed out, bounded in this field our extremest horizon. I do not remember that it ever occurred to us to inquire what, if anything, inflammation meant. It was enough for us to fight the battles of the hour; to remember if we could the phenomena and the lesions; and to keep the classifications from getting mixed.

But the formulation of the new bacteriological technique and the deeper study of the infectious diseases in which inflammation is frequently a prominent feature, brought new light and fresh impulse into the study just then drifting rather aimlessly in the eddies. I think, too, that we shall not readily overrate the importance as a stimulus, here as elsewhere in pathology, of the practical awakening of the medical world at this time to the fact that, superior as in some ways he is, and occasionally enjoying a bank account, the man physical is pretty closely linked from the cradle to the grave with lower life forms in ways which could not longer be ignored. And the hospitalities which we were forced to accord to the bacteria and to protozoa in our scientific housekeeping did much, I think, to foster the wider outlooks and the more intelligent and practical recognition of fundamental laws which chemistry and physics had long since formulated, and the study of organic evolution had revealed, when these were at last seen to bear not remotely but directly upon the more subtle problems with which we now stood face to face.

There is an interesting story in the drift of events at this period which I have not time to tell. But the fresh point of view led away for the moment from our descriptions and our catalogues of inflammation as it occurs in man, down to the study of analogous phenomena in lower and simpler forms of living things.

That trusty old pal of the physiologist, Amœba, was lured from his seclusion and injured in a variety of ways which resemble the injuries known to initiate most often the inflammatory processes in man. He was prodded, bruised, cut—actually vivisected, I shudder to say. He was supplied with strange, barbarous diet; microbes were set upon his trail. And when Amœba didn't succumb, the ways in which he held his own and the processes by which he responded to injuries were carefully noted. In the word injuries I include those toxic injuries which micro-organisms can inflict, and which are on the whole more frequent and important than the cruder physical injuries to which man and his lowly brother are alike subject.

Then other simple forms of living things were brought upon the stage and the conditions which determine amœboid movement were investigated. It was found that while the range of stimuli is limited in response to which under normal conditions amœboid movements occur, in abnormal conditions a similar response is elicited by the most varied agencies which for better or worse can lure or repel the elementary organism. So chemotaxis began to figure in our books along with phagocytosis and emigration.

It thus had not been necessary to extend this new line of study beyond a few elementary living organisms, which had been submitted to chemical and physical injuries, before we had a suggestive clew to the explanation of one of the most significant phenomena of exudative inflammation. This clew, if formulated, would be something like this. The physiological capacities of simple cells acting as independent organisms are capable under abnormal conditions of responding in an altered or exaggerated manner to unusual stimuli in ways which protect the organism against diverse forms of injury. Thus amœba, for example, by means of its digestive processes can protect itself against pathogenic microbes. In this protective response to an actual or impending injury, amœba no more makes use of newly acquired capabilities than does a man who kicks a predatory dog indulging or threatening some sinister raid upon his shins.

Then the study turned upward, and bits of old lore, which had been gleaned and catalogued and stored away and forgotten, because at the moment their meaning was not clear, were dug up again and patched into the new mosaic. To be brief about it, I may say that it was found that as we rise in the scale of being, from those organisms which consist of a single cell to multicellular forms and then on up through the series in which the structural differentiation of cells and organs keeps pace with the physiological division of labor, until we reach the very highest, we find that there still remain—and here is the heart of the matter from our present standpoint—there still remain some cells which have shared but little in the changes involved in the physiological division of labor. These have retained such simple and varied capacities as belong to lower independent organisms. Such cells, as you know, are the connective-tissue cells, including endothelium and especially the leucocytes. It was not long before it had been shown that under similar conditions these undifferentiated cells of the higher beings respond to injuries physical and chemical very much as cells do which are wholly independent organisms. Now assuming that the success of these lowly cells in the body in resisting injury and in destroying injurious material—for such, in common with amœba, appears to be one of their capacities—tends to foster the welfare of the body at large; we seem to have won at last a reasonable basis for an hypothesis around which to group facts at least, if not to explain the phenomena of suppurative inflammation.

I cannot permit myself to go further in this direction, nor to suggest ways in which other elements of the exudate than the leucocytes may contribute in their new forms and situations to the welfare of the individual. Nor is there time even to enter upon those phases of inflammation which directly contribute to permanent and extensive repair.

I am not quite certain that we know enough yet to define inflammation concisely; there are so many phases of it and of the life of the body at large which may modify its manifestations and about which we are almost wholly ignorant. But I think that we shall gain some definiteness of conception, some clearness as to most urgent lines of research, possibly—although I have not for the moment that much at heart—some immediately practical hints, if we fall in with Adami's suggestion, and characterize inflammation as "the series of changes constituting the local manifestation of the attempt at repair of injury," or briefly "the local attempt at repair of injury."

This far-reaching conception of inflammation as a conservative process in which the body cells adapt their physiological capacities to changed conditions, does not at all supersede, but does co-ordinate, the old catalogues and classes of phenomena and lesions. We may keep our exudative, hemorrhagic, necrotic, croupous inflammation, if we like. We can even drag out the dear old *tumor*, *rubor*, *calor*, and *dolor* and reverently dust them off if we be so inclined. These things may be still of practical as well as academic value. But the clew which we have won to the meaning of it all is that which, as it seems to me, particularly marks the drift and purpose of pathology in this field to-day.

Of course, it may not strike the surgeon as a happy conception that one of the phases of disease of which he stands most in dread, and the suppression of which in these later days it is one of his greatest triumphs to have achieved, should be at bottom conservative in its nature. Nor will the physician perhaps find it easy to think of tubercle as in truth a triumph of conservatism. But after all we must not forget that this new conception of inflammatory processes and lesions does not imply the belief that the body always, or even ever, succeeds in obtaining the best conceivable results in these conservative responses to injury. But when we reflect that its achievements in this direction are only the result of emergency measures, in which the body adapts as best it can machineries and powers maintained for other uses; if we remember that excessive stimuli may incite excessive response; that especially unfavorable conditions may turn its powers and mechanisms awry—we shall, I think, find it possible to admit that we cannot justly count the failures as legitimate ground for total dissent from the point of view to which I have directed your attention. There are many other phases, which I have not time to consider, of this which Welch has happily called adaptation in pathological processes.

If I am not making too large a claim upon your time and patience, I should like to call attention to one other theme, namely, the inciting factors in tumors.

It would certainly seem at first glance that in considering tumors we shall not need to be warned against the traditional error into which medical men as well as others have so often fallen, that of conceiving of disease as a thing. For surely our fundamental notions of tumors and even our very definitions imply that they are things, circumscribed tangible structures; objects which we can cut away. But here again the tumor is not the disease; it is only one of the results of the disease, just as pus is not inflammation but only one of its typical products. Disease is here, as always, a process, and although in this case the morbid process which leads to the formation of the tumor is masked by the tangible result, it must not be ignored in such a point of view as we are now striving to attain. And thus it is that when we speak of the alleged causes of tumors we do not really mean causes at all, but the inciting factors of the processes from which the tumor results.

This distinction, fine and possibly finical as it may seem, is not unimportant, because, as it appears to me, there is no field in pathology in which the alleged causes of disease, which are solemnly arrayed in treatises and lectures under the heading of etiology, fall so wide of the mark as just here among the tumors. From bumble-bee stings to clay pipes; from aberrant cells to postulated parasites, we lay these motley things and circumstances in a row before our pupils with a complacent smile; as who should say the veriest dunce cannot fail to see that since tumors occasionally, or frequently, follow these local visitants, here be veritable causes.

One may have a more or he might have a less profitable employment than speculating upon the reason why the cells of the human body do not go on growing indefinitely in size, instead of stopping as they always do when they have reached certain moderate dimensions. And if one had for a moment no better business than this inquiry, he might learn that others also had been engaged at various times in the same occupation. He might learn, further, that a clew to the answer had been reached. That clew is to this effect: cells being supplied with nutriment from without by absorption through their surfaces, a certain proportion must be maintained between the bulk of the material to be nourished and the absorbing surfaces. But as bodies increase in size the superficial area does not keep pace with the mass, so that in the case of cells the nutritive balance is disturbed and growth ceases. Of course, this may occur sooner in some cells than in others, but it occurs so early in all the body cells that these rarely get beyond the microscopic limit. And that appears to be one reason at least why cells don't grow as big as grapes or pumpkins.

If, on the other hand, we consider a more complex organism as a whole, one made up of many and of diverse cells and cell groups, we fail to find in this simple nutritive factor any reason why a mouse, for example, should not grow to be as big as a man, or a man as big as an elephant; since we cannot give any reason, so far as I know, why the kidney, for example, could not have a hundred times as many cells as it has. If asked to account for this, we naturally and properly fall back upon the inherited capacities and limitations of the species, and either dismiss the inquiry so, or, like the learned judge in "Nathan the Wise," summon our interlocutors to appear again in a thousand thousand years, when there will be more likelihood of an answer.

But—and now mark well how familiarity breedeth contempt—when all of a sudden some part of the body, with its inherited limitations like all the rest, begins to grow and keeps piling cell on cell until the new production, a tumor, is sometimes so massive in proportion to the tissue from which it sprang that an elephantine man would be but a petty wonder in comparison—well, under these conditions we come at the solution of the identical problem which we had so dexterously shirked or so ruthlessly handed to posterity with a club or a sting, with an ulcerated tooth or the butt of a clay pipe.

When we prate of hereditary predisposition as the cause of tumors, we simply beg the question. When we urge local excesses in cell nutrition we are reckoning without the host.

In truth, without pursuing this quarry to cover, we are not, I think, likely to apprehend the real cause of tumors until we approach the subject from the standpoint of the cell itself—until we know much more than we do to-day of the subtle influences which determine the vigor or the feebleness of its nutrition and its growth; the inexorable sway of its heredities; the factors which control its proliferations and its degenerations; and, perhaps more than all, that interdependence of closely or remotely related cells which makes the living body an organism and not a simple congeries of autonomous units.

The cell capacities, complex and varied as they are, have been very firmly fixed by untold generations of environmental influences, and are extremely tenacious of their birthrights. They are doubtless to-day, as they have always been, and as all other living things are, subject to sway and variational drift. But these influences become evident only after long periods. How then can we conceive of a fundamental alteration in cell capabilities as the result of a momentary trauma?

Of course what we mean when we cite our hodgepodge of traumatic agencies as causes of tumors is, that a long-continued slight local injury or a more acute or positive damage may in some way alter the local conditions of cell life and growth so that the proliferative capacities of the cells can come into play, in a fashion determined by their antecedents.

The new cell lore has, indeed, widened our outlooks in the possibility of profitable study of the minute morphology and physiology of tumor cells, though we can hardly surmise to-day whither it will lead. But until we gain clearer vision in the normal fields, which are hardly yet opened, we cannot, I think, reasonably expect to fathom the subtleties of the abnormal. So I hold one offer open to all comers: If any one will tell me by what arrangement of cell mechanism, by what disposition of cell impulse, under what direction of heredity or environment, the various cells of the normal body go on growing, multiplying, taking on new forms and functions, framing new tissues, from the time the original cell ceases to be an egg and becomes an individual, until full maturity of the body is attained—if any one will tell me this, I say, and then tell me why at maturity this tissue growth ceases, why these new adventures in organ-forming stop, and from maturity until the worn-out body is ready for the grave only those growths and replacements occur which are demanded by the exigencies of nutrition or by accidental emergencies, I will agree to hand him back his lore as a fair clew to, if not an exhaustive exposition of; the origin of tumors.

I cannot think of tumors as a superior sort of inflammation. I cannot understand to-day cell and tissue formation in response to the presence of microbes, except as a protective effort against an injury. And so, finally, I fail to conceive how the development of a complex and elaborate structure, almost organoid in character, such as we have in adenoma and carcinoma, for example, should be required, if protection against a microbic injury be the outcome of the process. Certainly I recall no analogy for this conception in the varied responses to such injury with which we are already familiar.

It is possible that in some inflammatory growths now grouped among the sarcomata microbes may be found which are capable of setting the cell impulses astir. This has not yet been done. Nor are there, in my opinion, any sufficient or even promising data at hand for the belief that microbes of any kind are the inciting factors in any honest tumor. I do not say this cannot be; but only that we have to-day no proof. I look upon this notion as one of the numerous chalk eggs whose shaping an uncritical estimate of the bacteriological era has encouraged, and on which the spirit of discovery will, I fear, brood for a long time without quickening.

It was the uneasy consciousness of the futility of the commonly urged so-called causes of tumors which led to Cohnheim's hypothesis of aberrant embryonal cells or cell masses. But it soon became clear to the critical that this did not help the matter much, if at all, because, admitting his postulated cell strays, you are no nearer to the reasons for their sudden growth after various periods of dormancy.

Virchow always, if you will permit the crudeness of the implication, had a choice assortment of conceivable cell stimuli up his sleeve, nutritive, functional, and formative. So that it was not very difficult for him, when he came up against pathological new formations, to mix, in theory, a judicious quantity of nutritive and formative stimulus with the body, to which the cells would, in theory, dutifully respond. This did well enough for simple tissue growths. But when he came to account for such complex affairs as cancers, he was forced either to brew a particularly choice thing in stimuli, which he was fain to call "specific" in consonance with the specific growth which it was to determine; or to assume specific qualities in the tissues themselves, which he called "predisposition." He concluded—clever Virchow!—that for his part he felt safer to keep a string on both possibilities.

In later times, Hanseman has based a rather ingenious hypothesis of the origin of tumors on alleged irregularities in mitosis—a standpoint difficult to share for those who keep in mind the ancestral traits which hold every living cell of the human body in most rigorous restraint.

The most common attitude to assume—and perhaps this is at once the most imposing and the easiest—is to say that the reason why tumors occur is because the proliferative capacities of the cells are increased; and then refrain from further fruitless prying.

More subtle conceptions of the origin of tumors are, however, much in evidence in the thought of the day in pathology. Ribbert, of Zurich, has perhaps more definitely than any other framed a working hypothesis which is clever and suggestive; though, like any hypothesis which essays to bridge abysmal ignorance, it is likely to lead to Omar's plaint that we "evermore come out by the same door wherein we went." Ribbert lays great stress, in his conception of the origin of tumors, upon the intimate associations of the cells as parts of an organism, and believes that their varied capacities are normally held in some fashion under mutual restraint in subservience to their common welfare. This mutual relationship however once destroyed, for example by the separation of cells or cell groups from their organic associations, their physiological capacities are no longer held in leash, and if the nutritive and other conditions be favorable may express themselves in exaggerated fashion without the actual acquirement of new capacities for the transformation of energy. This restrained state of the cells under ordinary conditions Ribbert calls tissue-tension ("Gewebsspannung"). As I understand it, the state of affairs is in Ribbert's conception something like that of a lot of active, healthy boys in a schoolroom who have a great deal more energy than can for the welfare of the whole school be safely released. Turn some of them out of doors, and they do not develop any more capabilities for roaring, shrieking, fighting, and making themselves generally offensive than they had before; only these now find expression. What Ribbert would call the schoolroom tension is relaxed. In neither the cells nor the boys do we need to assume new or exaggerated capabilities to account for the result of organic disassociation.

Ribbert goes further than this, and explains in a rather convincing fashion the way in which he conceives the process of cell disassociation and release from restraint to occur. Since he does not admit an increase in the inherent proliferative capabilities of the cells, he cannot assume, as is commonly done, that the process is initiated, in carcinoma for example, by the epithelial cells. He assumes and adduces very striking evidence for his assumption that the process starts in the connective tissue, which, as we know, is very liable to increase in amount in response to a variety of influences, notably those which involve trauma, or simple inflammation, or replacement hyperplasia. In the starting of carcinoma of the stomach or intestine, for example, Ribbert shows that, in many cases at least, the new-formed connective tissue cuts off cells or cell groups from their organic connections, and claims that in this way alone we may account for the required release from the restraints of his "tissue-tension."

Numerous objections have been urged to these conceptions of Ribbert. But they are highly suggestive at least, and I call your attention to them here because they illustrate the tendency in modern pathology to seek for explanations of abnormal phenomena in more subtle agencies than we have hitherto been wont to recognize. In our efforts to comprehend such obscure abnormalities as lie at the bottom of the origin of tumors, as of other diseases, I think that it would be wise if we were at least to hold in mind the possibility that a vague group of physiological factors which we dimly conceive of through the so-called internal secretions may be of significant influence even in local manifestations of disease.

Notwithstanding these new outlooks to which I have called your attention as illustrations of the general drift, pathology in its immediately practical phases still moves on in the beaten paths. Many of the most significant diseases still await competent study along the old objective lines and do not as yet admit of adequate hypotheses. We have caught glimpses here and there of important physiological capacities which we as yet hardly venture to name, much less understand. The inciting factors in many of the most dreaded and serious infectious diseases are wholly unknown. So the pathologist will continue his search for pathogenic micro-organisms; he will go on making autopsies for the practitioner, and simple diagnosis will mostly be his not altogether inspiring aim. He still will veil as best he can his grief when the inexorable exposures of the autopsy fail to confirm the convictions of the bedside. He will still strive to evince a subdued if not enthralling interest in tacking names to tumors removed from persons whose past or present he knows not, and whose future he will never learn. This he will do, not so much because there is any scientific interest to him, as a rule, in his performance, as because so only can he gain material for study or for academic purposes.

One great practical result of this busy quarter of a century in pathology is the getting together into useful form of a series of tests and methods by which the practitioner can secure greater accuracy in diagnosis and greater precision in treatment than was possible in the earlier days. These new methods in diagnosis, requiring considerable technical facility and some experience, now form a compact discipline which has been called "clinical microscopy." "Clinical pathology" would, I think, be a better term. Although strictly a practical adjunct to the work of the practitioner, clinical pathology still largely remains in the hands of the pathologist. This condition of affairs may be wise, and certainly must be convenient—for the practitioner. But it involves the pathologist in a series of the least interesting and most time-consuming tasks, diverting him from lines of work along which lie his most cherished outlooks. To ask the professional pathologist to continue the practical administration of these diagnostic tests is, to borrow an example, somewhat as if one who should seek for advice about his diet from his physician were then to request the doctor to digest his food.

I think that this matter is of the utmost importance in hospitals which have an officer called a pathologist, who is, however, at present usually almost wholly occupied in assisting the practitioner in diagnosis. This is useful work, indeed, but the pathologist is in consequence almost wholly debarred from pursuing those lines of research which it is the privilege and duty of hospitals to encourage and maintain. It seems to me that physicians, who constitute the medical boards of hospitals, might wisely urge the creation of an office which may be called an interneship in clinical pathology, whose incumbent could, under the direction of the pathologist perhaps, be responsible for much of the routine work in laboratory diagnosis.

If I have succeeded in my purpose in these glimpses here and there in pathology, you will realize, as indeed you may all have done long ago, for I have not aimed to present new things to you, that pathology has set for itself in these later days problems which involve far more subtle conceptions of the cause and meaning of disease than were possible when we entered upon its study a couple of decades or so ago.

We have seen that the cell is not a mere lump of jelly with curious chemical proclivities, but a most complex machine. The microbe has set the door ajar to a vast arena of beneficent study. But it no longer claims an exclusive rôle in the drama of infectious disease. It is indeed often the sinister and necessary villain on whose capacities and deeds the plot hinges, but it is by no means the star performer and is as certainly not the play.

Bacteriology, the foster child of medicine, has grown so lusty and exacting that we are eagerly acquiescent in its partition among those who love it for its own sake, those who cherish it for the light which it casts into other fields of science, and those who prize its economic aspects; reserving for ourselves only those relatively limited, though highly important, phases which bear upon the metabolism of the body and the incitement of disease.

We have begun to realize in a practical way that molecular constitution, the laws of osmosis and the diffusion of gases, gravitation, elasticity, and pressure are all physical factors in the structure and work of the body which we must reckon with in disease as well as in health. We have learned to perceive in inflammation something more than a vexatious episode in the life of man or an exhaustless stimulus to descriptions and catalogues. We find ourselves forced to look for light on the etiology of tumors past the crude incitements with which the academic juggler has been wont to toy, to those deeper phases of cell life and impulse which it remains for future workers to unveil.

We realize clearly to-day that the man with whom we deal does not stand for himself alone, but is the outcome of ages of adaptation to changing environment, whose record we may spell out not only in his normal state, but in the stress of disease, when capacities and vulnerabilities, which do but rehearse the story of his slow evolvement, stand out now with sinister and again with beneficent import.

Pathology is now passing out of the stage in the development of a science which is marked by the simple accumulation of facts. We are "grouping whole series of phenomena as diverse manifestations of identical forces due to diverse conditions of environment." We are even gaining courage with Schleich to describe disease as "a form of the struggle for existence against those injurious influences to which man is not yet adapted."

If one were asked to summarize the most important change in outlook and purpose which has woven itself into pathology during the past half-century, I think that he might wisely say of disease as Conn has recently said of animals and plants, namely, that fifty years ago they were objects to be classified; to the student of to-day they are objects to be explained. Of course, medicine has had explanations a plenty which for exhaustiveness and finality left little to be desired; ranging as they have from black-bile to Beelzebub. But there is just one fundamental difference in our attitude to-day which lends assurance to the hope that we are in the right way at last. That is, that we are no longer trying to conduct alone our search for light, but have called in our sister sciences. We have at last linked our conceptions of the forces which sustain and sway the human organism with forces which are universal. And when we get conceptions which fit in with the laws of the conservation and transformation of energy, with the doctrines of organic evolution, and the formulas of molecular physics, it is, I think, a good deal more than an even chance that we are on the right trail.

When I recall the severely objective and intensely practical character of the meetings of this society in which it has been my privilege to share, I am more than a little dubious as to the pertinency of my theme. So I shall not think it strange if you regard this essay as less an exercise in scientific exposition than an indulgence in the gentle art of babbling.

CYSTITIS DUE TO THE TYPHOID BACILLUS INTRODUCED BY CATHETER IN A PATIENT NOT HAVING TYPHOID FEVER.

By THOMAS R. BROWN, M.D.,

BALTIMORE, MD.

From the discovery of the bacillus typhosus by Eberth [1] up to within a comparatively recent period, a rather limited rôle has been assigned to this micro-organism by the great majority of medical men. Nevertheless isolated observations made from time to time presaged our modern views of this bacillus, and now we know that it plays a much larger part and has a much wider significance in bacteriological investigations than was formerly supposed. Many cases of a true general infection with this bacillus have been described, while numerous observations have been made of its presence in the spleen, in the rose spots of the typhoid eruption, in the lymph glands, in abscesses and periosteal swellings, and in many hitherto unexpected locations.

Among the most interesting and, from the hygienic point of view, most important places in which it has been found is the urine. Even shortly after Eberth's discovery of the bacillus a few cases of the finding of the micro-organism in the urine were reported. Bouchard [2] in twenty-one of sixty-six cases of typhoid fever examined found albumin associated with bacteria, which he assumed to be typhoid bacilli; Hueppe [3] in one of eighteen cases; Seltz [4] in two of seven cases, in both of these associated with albumin and in one also with casts; Konjajeff [5] in three of twenty cases, calling especial attention to the fact that they appeared during the later stages of the fever and were always in large numbers, if present at all, and regarding the presence of

[5] Ref. in Cent. f. Bakt., 1889, vi., 672.

the bacilli in the urine as evidence of typhoid lymphomata in the kidney.

Karlinski[1] in forty-four cases of typhoid found the bacilli present in the urine of twenty-one, always associated with albumin and always in pure culture; Neumann[2] in forty-eight cases found the bacilli eleven times, and was the first to call attention to the danger of the urine in the spread of the disease, especially as the bacilli remained in the urine in many cases for a long period of time after the cessation of the fever, and that they could be present in a urine otherwise normal, *i.e.*, without casts or albumin.

Melchior[3] reports a case (Case IX., 1892) which developed all the typical symptoms of cystitis fourteen days after the cessation of typhoid fever, from the urine of which he cultivated the typhoid bacilli in pure culture; in this case the condition cleared up entirely in twenty-two days without treatment. He also reports a case of post-typhoid cystitis due to the bacillus coli communis and one of typhoid with associated nephritis, in which Eberth's bacillus was found in the urine.

Borges[4] found the bacilli in three of ten cases, but in three others found albumin, thus showing that the finding of the latter was no evidence of the presence of the former; Blumer[5] found the typhoid bacillus in only two of sixty cases examined, while Baart de la Faille[6] found the bacillus four times each in twenty-seven cases examined, Blumer suggesting that the bacilli might possibly reach the bladder from the intestinal tract by penetrating the recto-vesical wall. Krogius[7] found the bacillus in a case of post-typhoid cystitis; Wright[8] in six of seven cases, and Besson[9] in six of thirty-three cases, in five of which albumin was present in considerable amount.

Rovsing[10] reports a case (Case LV. of his series) of cystitis with swollen and reddened vesical mucosa, following nephrolithiasis and typhoid fever, double suppurative nephritis, and right pyonephrosis, in which Eberth's bacillus was found in pure culture; the case had never been catheterized. All the above cases were reported previous to the time of the Widal reaction, and as this reaction seems to be the only absolutely certain means of determining whether or not a micro-organism is the typhoid bacillus, in many of the earlier cases the micro-organism present and regarded as the typhoid bacillus was probably the colon bacillus, although this chance of error is much less in the cases reported between 1895 and 1898, due to the use of the differential media of Elsner, Capaldi, Hiss, and others. In the cases reported since 1898 differentiation has been rendered comparatively easy by the application of the Widal reaction, and it is largely from these cases that we must derive our views concerning the prevalence of typhoid bacilli in the urine.

Richardson[11] studied the urine of thirty-eight typhoid patients with extreme care and for a considerable period of time; of these, nine cases showed the typhoid bacillus in pure culture, while in eight of the remaining twenty-nine other micro-organisms (in six the colon bacillus) were found; in all the nine cases in which the typhoid bacilli were found there was slight albuminuria, but this also occurred in fifteen of the remaining twenty-nine cases; thus showing that the presence of albuminuria is in no wise indicative of the presence of the typhoid bacillus; its absence, however, usually pointing to the absence of this micro-organism. The bacilli usually appeared quite late in the disease and generally persisted for a long while unless appropriate treatment was carried out; this treatment Richardson[1] considers to be the administration of urotropin, which he thinks is almost a specific in this condition.

Petruschky[2] found the micro-organism in three of fifty cases examined, and Horton-Smith[3] in three of seven cases, the latter calling especial attention to the fact that the fæces were particulaly dangerous as a disseminator of the disease in the early, the urine in the later stages—often, in fact, long after the entire subsidence of fever.

Gwyn[4] reports seven cases in which the typhoid bacilli were present in the urine, usually associated with pyuria and signs of bladder irritation, while Schichbold[5] found the bacilli in five of seventeen cases examined, the latter observer concluding from the findings of the two of these five cases that came to autopsy that the presence of Eberth's bacillus in the urine is evidence that the case is one of nephro-typhus.

Two cases of especial interest are those of Young (personally communicated) and Houston,[6] both cases of chronic cystitis due to the bacillus typhosus, the case of the former being the first one of this nature of which I have any knowledge. In Young's case (to be reported in full subsequently), one of a chronic cystitis of five years' duration immediately following an attack of typhoid fever, typhoid bacilli were found in large quantities in the urine in pure culture, the micro-organisms not only showing all the characteristic cultural peculiarities, but agglutinating positively with typhoid serum; while, on the other hand, the patient's serum gave a positive reaction with the laboratory cultures of the typhoid bacillus. The patient was not cured at the time, and now, two years later, has reappeared, still showing large numbers of typhoid bacilli in the urine. The patient had never been catheterized. In Houston's case, the cystitis was of three years' duration and directly followed an attack of what was probably typhoid fever. A bacillus was obtained in pure culture from the urine, which culturally resembled the typhoid bacillus in every respect and also agglutinated with the patient's own serum in dilution of 1 : 100, while the same serum agglutinated the stock typhoid bacilli, but not colon bacilli. At the time when the case was reported, Houston had been unable to cure the condition.

The case I wish to report is a unique one in many ways; in fact, as far as its etiology is concerned, I have been unable to find one like it in the literature. The patient, Mrs. S——, entered the service of Dr. H. A. Keely, who kindly permitted me to study the case bacteriologically; she was operated upon for a large myomatous uterus on January 20, 1899. The only thing of interest to us in her past history was the fact that thirty-five years previously she had had an attack of typhoid fever; since that time, however, there had been no illness in the least suggesting a reinfection with typhoid, nor had there been any manifestations of the presence of the micro-organisms in bone lesions, periosteal swellings, or osteo-myelitic abscesses; there had never been at any time painful or difficult micturition. The operation, performed on January 20, 1899, was a difficult one, and there was considerable inevitable handling of the bladder and possibly some slight trauma of that organ. The urine, examined on the day of operation, was absolutely normal, of acid reaction, of specific gravity 1.021, with no trace of albumin or sugar, and showing under the microscope only a number of bladder epithelial cells, but no pus cells, casts, or bacteria. For eight days after the operation the temperature was practically normal, and the convalescence uneventful; on the ninth day, January 28th, the temperature rose to 100.4° F., and for the ten days following showed a daily rise to about 100° F., gradually declining after that time. On the day preceding the rise of temperature, the patient had complained of intense pain in the bladder, and the urine showed a dense sediment consisting of almost pure pus, with considerable albumin; the reaction was distinctly acid, and the specimen was of course obtained by catheter. Two days before this the urine had been examined, and had been found to contain a trace of albumin, with a few pus cells and a large amount of amorphous urates in the sediment. A cystoscopic examination made a few days later showed a universally congested vesical mucous membrane with no areas of ulceration.

The usual symptoms of acute cystitis, tenesmus, frequent and painful micturition, vesical pain, etc., were present in a marked degree for the first ten days after the development of the cystitis, after which most of the symptoms abated markedly except the frequency of urination, which continued up to the time when the condition was cured. The urine showed large quantities of pus, however, for a period of twenty-eight days, after which it disappeared quite rapidly, as will be described shortly.

On January 27th a specimen of urine was obtained under strict aseptic precautions, the method used being as follows: the external urethral orifice being carefully cleansed with bichloride-of-mercury solution, followed by sterile water, a sterilized glass catheter whose external end was covered by a sterile rubber cuff extending several centimetres beyond the end of the catheter was introduced, the fingers of the operator being allowed to touch only the distal end of the rubber cuff; the urine was allowed to flow for a short space of time, when the rubber cuff was pulled off by traction on its distal end and a small amount of urine was collected in a sterile test-tube, the cotton plug of which was of course immediately reinserted after the urine had been collected. A large series of control experiments with normal urines has shown that this method is absolutely reliable. An examination of the specimen thus obtained showed that, besides large numbers of pus cells, a few red blood cells, and many bladder epithelial cells, it contained large numbers of an actively motile, rather short, rod-shaped bacillus. Plate cultures on agar were then made, when it was found that the micro-organism was present in pure culture. Transplantations were then made on the various media, gelatin, potato, glucose-agar, litmus, milk, peptone, and bouillon. On gelatin the growth was white and fine, both along the line of stab and on the surface, while there was no liquefaction of the medium; there was no gas production in glucose-agar; milk was neither coagulated nor acidified; in peptone there was clouding but no indol production; on potato a very faint, whitish, almost invisible growth was to be made out, while the study of the bouillon culture, which was much clouded, showed that the micro-organism was markedly motile after forty-eight and even after seventy-two hours. A second culture made from a specimen of urine, obtained on February 16th in the same way as before, demonstrated the presence of the same bacillus in pure culture with identically the same cultural peculiarities, but in smaller quantity.

As the micro-organism so definitely resembled the typhoid bacillus in all its properties, the final test was made, *i.e.*, to see whether or not it would agglutinate with typhoid serum. The person from whom the serum was obtained was a patient at the Johns Hopkins Hospital who had an absolutely typical case of typhoid fever, with palpable spleen, typical roseola, characteristic temperature, etc., and her serum gave an unquestionably positive reaction with the stock laboratory cultures of the bacillus typhosus. Both cultures in my case, that of January 27th and that of February 16th, reacted with this serum in the most typical manner; in dilutions of 1 : 20 clumping was marked in five minutes and complete in twenty minutes, while in dilutions of 1 : 80 clumping was noted in ten minutes, positive in thirty minutes, and complete in sixty minutes.

The patient was treated at first by bladder irrigations of borax and sodium bicarbonate solution, but although showing improvement under this treatment as evidenced by the decrease in the amount of pus, the quantity of albumin, and the number of micro-organisms, this improvement was so slow that urotropin, gr. v. by mouth three times a day, was given, and under this treatment the urine rapidly cleared up. Seven days after the inauguration of this last treatment, on March 4th, the urine, obtained in the same way as before, was found to be sterile, although there were still some pus cells present, and even a few on the day of the patient's discharge, four days later. The urine was acid throughout the whole course of the disease and was markedly turbid during the height of the infection.

As to the mode of infection in this case there are two possibilities: first, that the bacilli had lain dormant somewhere in the system since the attack of typhoid fever thirty-five years before; and second, that the bacilli had been freshly introduced.

Many reports have been made to show the great periods of time in which the bacillus may remain in various parts of the body in a latent condition, yet capable of starting up a reinfection if the circumstances are favorable. Flexner[1] has demonstrated living typhoid bacilli in an abscess between six and seven years after the occurrence of the original infection; Orlon[2] found the typhoid bacilli in an osteomyelitic swelling six and one-half months after the fever; while in periosteal abscesses the living bacilli were found by Melchior[3] ten and one-half months, by Chantemesse[4] fifteen months; by Buschka[5] seven years; and by Hübener[6] four and one-half years after all the symptoms of the disease had disappeared. Miller[7] has reported a case in which the living bacilli were found in the gall bladder seven years after the original infection.

Notwithstanding these examples of the marked ability of this micro-organism to remain latent for a long time, it is highly improbable, in fact almost impossible, to explain the present case on the supposition that the micro-organisms had lain dormant somewhere since the original infection. In the first place, the attack of typhoid fever had occurred thirty-five years before, and there had been no illness suggesting in the least a recurrence of the disease in the interim; in the second place, there were absolutely no evidences of any nidus in the body in which the micro-organisms could have remained latent; in the third place, there had never been any evidences of cystitis at any time previous to the present attack; and in the fourth place, the urine, carefully examined previous to the operation, was found to be absolutely normal. It is, therefore, highly probable that the bacillus was introduced into the bladder from outside, presumably by catheterization, the inevitable vesical trauma in such a difficult pelvic operation undoubtedly rendering the dangers of infection much greater. As far as I could learn, none of the nurses that came in contact with the case had recently been nursing typhoid patients. Nevertheless, when we consider the number of cases of cystitis produced by catheterization, relatively a small percentage perhaps, but absolutely quite a large number, and the variety of micro-organisms found as the provocative cause, it is not at all improbable that very occasionally Eberth's bacillus may be this cause, since it is a micro-organism of quite wide distribution and of undoubted pyogenic properties, and I have no doubt that with a complete bacteriological examination of all cases of cystitis, a few of this nature would be found. Perhaps, in this case, the fact that the patient had already had typhoid fever and was presumably more resistant to the infection, perhaps a diminished virulence on the part of the micro-organism, caused the infection to be so localized and prevented its spreading.

This case—a unique one so far as I know—adds but another to the ever-increasing list of pathological conditions which may be produced by the bacillus typhosus, and once more calls attention to the necessity of applying modern bacteriological, chemical, and microscopical methods to the study of conditions whose etiology has hither been unrecognized, for it must be mainly through these channels that light will be thrown upon many of the "dark continents" still remaining in clinical pathology.

A MEANS OF ACCOUNTING FOR GAUZE LAPAROTOMY PADS.

By VICTOR COX PEDERSEN, A.M., M.D.,
NEW YORK,
HOUSE SURGEON, SECOND SURGICAL DIVISION, NEW YORK HOSPITAL.

The final responsibility for instruments, sponges, gauze-pads, and dressings used in or about the body cavities legally rests with the operator. Although nothing will compensate for a very careful search of the field just before the wound is closed, any simple procedure which will secure their more reliable accounting must be valuable. Perhaps the article most frequently overlooked is the laparotomy sponge, or its substitute, the gauze-pad. The following means and method have very recently been devised by the writer, and used in the New York Hospital sufficiently to demonstrate that they are capable of furnishing accurate verification of the number of pads used in or about a laparotomy wound.

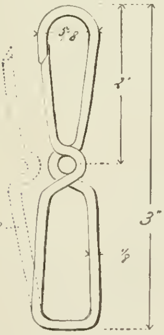

Fig. 1 A

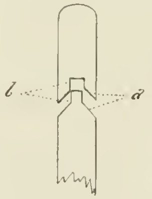

Fig. 1 C

Fig. 1 B

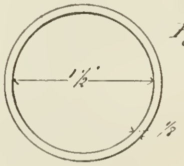

Fig. 2.

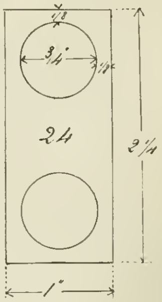

Fig. 3.

I. Of the means: *a*, The usual gauze laparotomy pads, with a tape from twelve to fourteen inches long securely sewed to a corner or an edge; *b*, "tally snaps," or their substitutes, namely, "tally rings," "tally checks," or artery clamps; *c*, "keepers," of either continuous or divided ring, continuous or divided oval, or fenestrated bar form.

II. Of the "tally": Fig. 1 gives the details and the dimensions of the "tally snap"; side view, A; edge view of the jaw side, B; interlocking of jaws, C. They are made of one-eighth inch diameter bright spring-steel wire, nickelled and burnished, bent as shown to avoid all joints, and can be very readily and thoroughly cleaned. The snap open for cleaning is shown in the dotted line, Fig. 1, A, *a*. Rigidity against opening laterally is gained by the overlapping elbow in each jaw (Fig. 1, C, *a*), and by the specially firm interlock of the jaws, Fig. 1, C. The bevelled edges, *a*, of the male and female parts aid rapid locking, while the straight sides, *b*, of the tongue and socket hinder lateral displacement. Fig. 2 shows the measurements of the "tally ring." Fig. 3 suggests a form of "tally check," which is like a trunk check, burnished nickel finish, with a hole in each end. One hole receives the tape and the other the keeper.

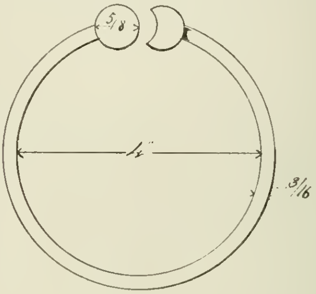

Fig. 4

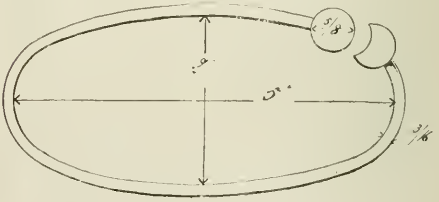

Fig. 5

If desired, any form of tally may be stamped with a number as shown on the check above. The objection to this is that it is almost impracticable to hand anything in series during an operation.

III. Of the "keeper": Fig. 4 shows the features of the divided ring "keeper," Fig. 5 those of the divided oval "keeper," Fig. 6 those of the bar-form "keeper." The continuous ring and the continuous oval "keeper" are of the same size as those divided. Otherwise no description of them is needed. The material is nickelled and burnished bright spring-steel wire, three-sixteenths or a quarter of an inch in diameter. The clasp of the divided keepers may consist of two spheres, five-eighths of an inch in diameter, one countersunk deeply to seat the other. A better lock is illustrated in Fig. 7. An olive-form button drilled through its long diameter is screwed for half its length on one end (1) of the wire. A slot is then cut from one side into the remainder of the central hole and its edges are bevelled to facilitate rapid seating. Into this slot the other end (2) of the wire is received. This form of lock can be managed with one hand by compressing the end 2 away from 1 as indicated by 3, and then letting it spring back. The two-sphere type of lock usually needs both hands for rapid working. Fig. 6 states full particulars as to the fenestrated bar-form "keeper." It has the advantage of maintaining the tapes separate and spread out, not massed as occurs with the rings and the ovals.

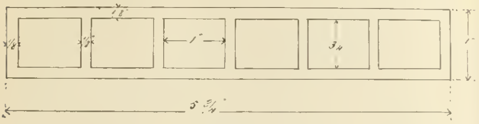

Fig. 6.

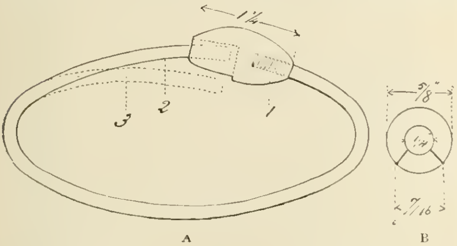

Fig. 7.—Trough Lock. A, Side view; B, end view (section).

The divided ring and the divided oval "keepers" are suitable for the tally rings, the tally checks, or the artery clamps. It may here be stated that the clamps are put upon the keepers by either of their handle finger-loops. The tally snaps may be used with any form of keeper.

IV. Of the method: 1. The number of pads and of tally snaps are known and recorded before the operation. 2. Two keepers are needed, one for each margin of the wound. 3. Each pad is handed to the operator with the tally snap securely tied to its tape. 4. While the operator is packing the pad away the assistant catches the tally on the keeper. If the bar-form keeper is used the first and second snaps must be put at its opposite ends to keep it horizontal. The subsequent tally snaps may be hooked into any convenient fenestra. Tapes twelve to fourteen inches long permit the keepers to hang well out of the operator's reach on the sides of the patient. 5. When a pad is removed from the field the tape is cut close to the tally snap. 6. The tally snap remains on the keeper till after the operation. 7. At this time the soiled pads and the tallies on the keepers are counted. The number of each should agree with that of the other. This identity in the number of snaps and pads is the first verification. 8. The second verification is the one usually made. The pads still clean are counted and their number is added to that of the soiled ones to obtain the total before the operation; so likewise with the tally snaps.

For instance: pads and snaps before operation 36 each; after operation, soiled pads 25, tally snaps on one keeper 10, on the other keeper 15, total 25. Hence all pads used in or about the operation are correctly accounted for—or the first verification is had. Clean pads 11; unused snaps 11; added to 25 each used, makes 36 each, the total of each before

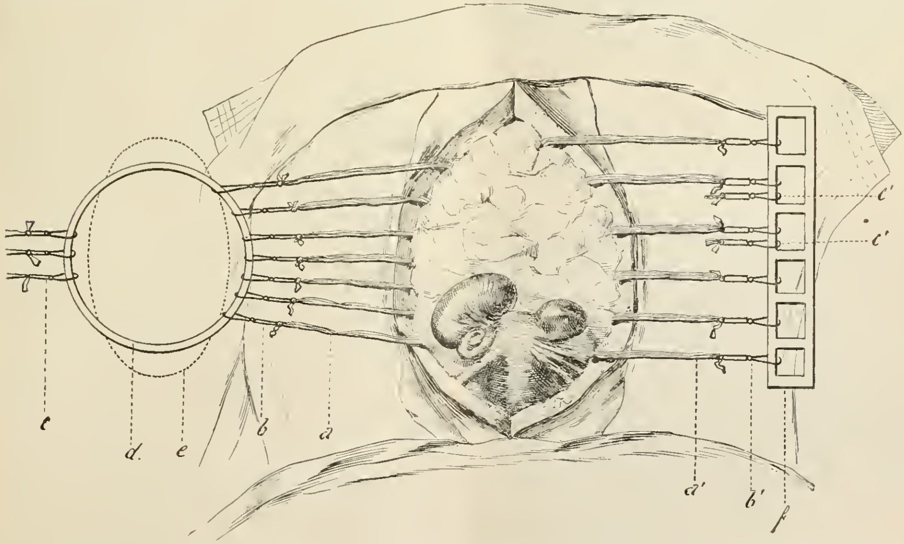

Fig. 8.—*a*, *a′*, Tapes, attached to pads and leading to snaps; *b*, *b′*, tally snaps, each securely tied to a tape; *c*, *c′*, tally snaps, with cut tape-ends attached, belonging to pads removed from the field, hence left on the keepers: *d*, continuous-ring keeper (drawn a little too large); *e*, continuous-oval keeper (drawn a little too large); *f*, bar-form fenestrated keeper. (The snaps on the ring-keeper should have been drawn massed close together, which is one objection to this type of keeper, as compared with the separation of them on the fenestrated bar.)

the operation. Hence the second verification is had. A careful negative search of the field will now make closing of the wound safe.

Fig. 8 and its explanatory notes will make plain an operation field with pads, tapes, snaps, and keepers.

No system is perfect. No means will make a final examination of the cavity unnecessary before closing it. The above plan is not perfect; but in actual practice it has been shown to furnish an accurate check on the number of pads used in or about the wound. It puts upon the operator's assistant the responsibility of attaching each snap to the keeper. This is easier than watching many tapes without keepers and with only artery clamps attached to prevent the tapes from being dragged into the wound, which clamps may themselves be used in error to clamp vessels. The keeper makes it impossible for pad tape and snap to get into the wound as has occasionally happened with loose artery forceps. The plan does not add any time to that of the operation, because the assistant can snap the tally on the keeper or cut the tape more rapidly than the operator can pack or extricate the pad, as the case may be. The great essentials are, first, that after a body cavity is open no pads be within the operator's reach except such as have tapes and snaps attached, and second, that each snap be promptly affixed to its keeper.

It is advisable to adopt a distinctive tally, something which can be used for nothing else, as can the artery clamp for hæmostasis in a hurry. The advantage of the tally ring and tally check over the tally snaps is that only the lock on each keeper needs attention as compared with the lock on each snap.

The general plan can be carried out fully by adopting any one of the above designs. It is hoped that service and security will be realized as fully as possible by it.

New York Hospital, December 1 1892.

Author's Note: Any one desirous of trying this method with very little outlay can buy several dozen large horse-blanket safety pins to use as tally snaps and make for himself any pattern of keeper he likes. Strips of galvanized, square mesh, railroad wire-fencing with meshes one by one inch will make excellent bar-form keepers. Ordinary large-sized safety pins are almost too small for safe use as tally snaps.

HISTORICAL NOTES ON THE SANATORIUM TREATMENT OF ALCOHOLISM.

By CHARLES J. DOUGLAS, M.D.,

BOSTON, MASS.

Apparently there is a notion prevailing in some quarters that the medical treatment of drug addictions—particularly alcoholism—is an idea that was originated within a decade or two by quacks and venders of secret nostrums. This supposition is far from correct. It is true, however, that during the last ten or fifteen years these exploiters of commercialism, with their secret and infallible "cures" for drunkenness, have made more noise than all the regular practitioners combined. Similarly, it may be said that Lydia Pinkham's face is more familiar to the general public than are the faces of the most learned and skilful specialists in diseases of women. But we are not justified in concluding from this fact that gynæcology is a specialty that originated with quacks, and that they only are now engaged in it.

While the recognition of alcoholism as a disease requiring sanatorium treatment by medical means is a modern idea, yet it long antedates the secret "cures." The honor of being the pioneer in this movement belongs to J. Edward Turner, M.D. His brain conceived and his zeal and industry established the first sanatorium in the world for the treatment and cure of alcoholism. His position was well stated by his lifelong friend and disciple, Dr. Valentine Mott, who in 1847 said: "In my professional life of over forty years I have accumulated facts enough to prove beyond all doubt that inebriety is a disease, affecting every membrane, tissue, and nerve of the human mechanism, producing in its victim a compound fracture from the crown of his head to the sole of his foot, as well as a mental and moral dislocation." As a result of the discussion aroused in the medical profession by the earnest and self-sacrificing labors of Dr. Turner, a petition was sent to the New York legislature in 1857 for the establishment of a State institution in accordance with his plans for the treatment of alcoholism. This petition was signed by over one thousand physicians. In it they said: "Without such an institution the physician has been compelled to turn from his patient, discouraged, disheartened, and defeated; and the victims of this painful malady—be they rich or poor, high or low, educated or uneducated—alike must find a drunkard's death and a drunkard's grave. With this institution we can save hundreds who are now crowding our insane asylums, inundating our courts, and perishing in our streets."

In the same year the Onondaga Medical Society addressed a memorial to the New York legislature on this subject, in which they said: "From a long experience in the duties of that profession which has brought us in daily contact with the victims of a diseased appetite, we have been forced to the conclusion that an institution in which the patient could be medically and morally treated would prove to be of greater benefit socially, politically, and charitably than any other institution of its nature in our land."

Up to that time there had never been in this country, or in any other, an institution for the medical treatment of alcoholism. In September, 1858, at Binghamton, N. Y., the corner-stone was laid of the first building ever used for this purpose. The ceremonies were conducted by a group of brilliant and famous men, and letters were received from the President of the United States and members of his Cabinet, as well as from many other distinguished officials. Edward Everett, then at the zenith of his fame, delivered an eloquent address on this occasion, in the course of which he predicted that the work begun by Dr. Turner would be taken up in other States and countries, until the principles here established would be utilized as a blessing to all mankind. His closing words were: "And believe me, many years will not pass away before it will appear that what you have just done for your own community, you have done for the civilized world."

This institution was operated with success for about three years, when it fell into the hands of the political Philistines, was wrested from Dr. Turner's management, and soon diverted to other uses. Nevertheless, the prediction of Edward Everett has proven true, that the medical treatment of alcoholism so ably and zealously advocated by Dr. Turner would prove a worldwide blessing. The pathological nature of inebriety is now universally recognized, and the profession is to-day giving more attention to its treatment than it did ever before in the history of medicine.

Like all pioneers who have blessed the world by forcing a new idea upon its attention, Dr. Turner's whole life was dominated by this one great object. No man has ever yet left a lasting impress on human history without exemplifying in his life the motto of the apostle to the Gentiles: "This one thing I do." Dr. Turner was animated by this apostolic spirit. From early manhood to the close of life all that he had or was or hoped to be—all his powers of mind and body—were laid, willingly and gladly, upon the altar of this one noble purpose. To teach mankind that alcoholism is a disease, and a curable one, was the object of his life. For this cause came he into the world; for this he lived, and for this he prematurely died. To-day he sleeps in an unmarked and forgotten grave, but the sons who build sepulchres to the prophets whom their fathers have killed will yet do him justice, and the day is coming when the world will crown him as one of the benefactors of the race.

The effect of Dr. Turner's work was immediately felt in many ways. Governor Andrew, in his annual address to the Massachusetts legislature in 1863, said: "Drunkenness is a disease as well as a sin. We have long since legislated for its punishment; let us no longer neglect to legislate for its cure. By every motive of humanity and reason, by every law of duty, it challenges our consideration."

In 1868, the Massachusetts legislature appointed a joint special committee, consisting of five members from the Senate and nine from the House, "to consider the matter of inebriety as a disease." These gentlemen brought in a long and able report, in the course of which they said:

"The position taken by those who have given this subject a special investigation in the light of all the facts which bear upon it, is that the continued use of alcoholic drinks produces a disease peculiar and distinct from all other diseases; having a distinct pathology, and presenting post-mortem appearances unlike those of any other disease, being as characteristic as those of typhoid fever or pneumonia. . . . The fact that inebriation is a disease, a mania, and that it is both acquired and hereditary, being conceded, the next practical question is, Have such cases heretofore been properly treated, and if not, what is the correct treatment? We know they cannot be successfully treated at home; they ought not to be associated with criminals nor with the insane; neither should they be neglected."

In 1870, Dr. N. S. Davis, one of our most distinguished medical men, who has since been called to preside over the International Congress of Physicians, said in a published address:

"If the inebriate is the victim of a positive disease induced by the action of an alluring and deceptive physical agent, alcohol, will any number of moral lessons addressed to his intellect, or any amount of denunciation hurled at his degradation and his vices, cure or reform him? Or will his arrest, arraignment in a police court, and extortion of the few dollars he has left, as a fine, eradicate the disease that is preying upon the most delicate parts of his organization? Abundant experience throughout the civilized world answers these questions in the negative. The treatment demanded by the nature of inebriation and the interests of humanity is the same in kind as that awarded to the sick and insane."

The many private sanatoria for the treatment of alcoholism now found throughout the country testify that the seed sown by Dr. Turner has taken root and is now bearing a beneficent harvest. I, of course, do not here refer to those widely advertised institutions where secret nostrums are used in a routine way, and where usually the attending doctor does not know the composition of the remedies he is employing—these having been sent to him from "headquarters," where they are secretly prepared. No self-respecting practitioner can countenance such a concern. But I have reference to those ethically conducted sanatoria where alcoholism is carefully treated by specialists in this disease, and where the physicians are concentrating their thought and study upon the best methods that scientific research can devise for its cure. To such a place a physician may take his alcoholics and be cordially welcomed as a consultant, and get any information he desires regarding the remedies employed in the treatment of his patients.

The secret "cures" referred to above are, however, rapidly disappearing. The most widely known of these had, a few years ago, three or four establishments in Massachusetts, each one doing an immense business. Now all of them are closed, with one melancholy exception, and that has but a small fraction of the patients it formerly treated. So far as I know, all similar concerns that were organized to exploit secret nostrums are either dead or dying.

On the other hand, it is gratifying to note that the professional and scientific sanatoria devoted to this specialty have greatly increased, both in number and efficiency, during the last few years. More patients suffering from alcoholism and other drug addictions are being thus ethically treated and cured than ever before. There are few chronic diseases more prevalent than these, and few that are more curable, and I predict that their treatment will soon be rated among the most important specialties in the medical profession.

Clinical Department.

AN INTERESTING CASE OF LABOR COMPLICATED BY UTERO-ABDOMINAL FIXATION.

By JOSEPH M. RECTOR, M.D.,

ATTENDING PHYSICIAN TO EMERGENCY HOSPITAL IN JERSEY CITY; GYNÆCOLOGIST, OUT-PATIENT DEPARTMENT, JERSEY CITY HOSPITAL.

E. A——, forty years of age, was the mother of six children, the first five of whom were born into the world after a normal labor, while the birth of the last was instrumental. The menstrual history was good. There were no indications of pelvic trouble or uterine disease either past or present, except as hereafter stated.

In January, 1897, the patient first came under my observation complaining of the usual indefinite train of pelvic and vaginal symptoms. I made an examination and found a lacerated and everted cervix, with complete procidentia of the uterus, relaxed vagina, and lacerated perineum. I advised operation as being the means of affording the speediest relief, but the request was refused, whereupon I replaced the uterus and inserted a large inflated rubber-ring pessary, supplementing it with the usual office treatment. The patient improved somewhat, and after a short time ceased visiting my office. I had no further trace of her until after the lapse of about six months, when she again called to see me, in the mean while having subjected herself to the operation as I before had advised.

In March of the present year she became pregnant. In April I was first called to see her, and found her suffering from continuous vomiting and at times severe abdominal pains of an intermittent, contractile type. Creosote and opium mitigated her sufferings, but she was compelled to use the same until the sixth month of her pregnancy. She was averse to being examined, and thus I was ignorant of her exact condition as regards what operation or operations had been performed, until the time of her labor, which occurred on Thursday, December 14, 1899. The contractions of the uterus began in the morning about eight o'clock and continued throughout the day. The expulsive efforts followed each other in rapid succession, and at six o'clock in the evening of the same day I was called in attendance.

Examination of the abdomen showed the scar of a median abdominal incision midway between the symphysis pubis and the umbilicus, while stretching downward from the upper extremity of the scar was a broad, tense band of tissue which could be easily felt beneath the skin, marking the adhesion between the fundus of the uterus and the abdominal wall. During the contractions of the uterus, the over-developed posterior wall could be recognized, while the normal fundus and anterior wall below the adhesion were poorly developed and flabby, making no attempts at contraction or expulsion, but on the contrary forming a pouch into which a portion of the fœtus was forced and which rested upon and lay in front of the symphysis pubis. Vaginal examination was unsatisfactory until an anæsthetic was given. Nothing could be felt with the first and second fingers in the vagina. Upon insertion of the entire hand, an opening was felt at the vault marking the orifice of the cervical canal, the entire vaginal portion of the cervix had evidently been amputated. The opening in the canal with difficulty admitted the index finger, although pains had been continuous for the past ten hours. The internal os uteri was drawn upward with the vagina, resting about two inches above the sacral promontory and pointing directly backward. The occiput was presenting in the fourth position, and between the right parietal bone and the symphysis pubis could be felt the feet of the child. Passing the hand upward along the legs I found them flexed at the knees and resting upon the symphysis, while the thighs and pelvis were contained within the pouch above described and resting in front of the symphysis.

The anæsthesia was pushed to the full surgical degree. Complete dilatation of the remaining cervical canal was accomplished with the hand, and the membranes were ruptured. I deemed it inexpedient to deliver the child by the presenting part because of its failure to have already engaged the inlet, the existing complications, and the dangers to the child of a high instrumental delivery with an unmoulded head; therefore, after pushing the head upward and the lower trunk from within the pouch, I performed podalic version, and a living child was brought into the world. Confining my attention to the mother, I gave the partially asphyxiated child to Dr. Immanuel Pyle for resuscitation.

The hemorrhage following the delivery of the placenta was enormous. The uterus contracted but feebly; that portion above the adhesion contracted slowly, while the lower anterior portion did not contract at all. Hot diluted acetic acid was thrown into the uterus, while continuous manipulation was made from without; the upper posterior portion responded, but the lower anterior did not. Ice was then passed up into the pouch, and it at once contracted, thus causing the hemorrhage to cease.

After half an hour's continuous efforts Dr. Pyle succeeded in resuscitating the child. My attention was called by Dr. Pyle to the peculiar cry of the baby, and an examination revealed to us a deep depression in the skull over the right frontal region and a corresponding condition in the left occipito-parietal region. These depressions marked the points of compression in nature's attempt at natural delivery.

It has seemed best to me to report this interesting case, thus adding another proof in evidence of the disturbances which may arise from the formation of adhesions between the uterus and abdominal wall in child-bearing women. Such patients' suffering from symptoms referable to retroflexed, retroverted, or prolapsed uteri certainly call for some means of cure or relief, but when to accomplish that end we are obliged to jeopardize and endanger their future lives, and that of their unborn children, it becomes our duty to consider carefully before we act. The operations of Goff, Alexander, Mann, Edebohls, Wylie, Dudley, Kelly, and many others are far preferable, and in the end may save many lives for some more useful purpose.

A REMARKABLE CASE OF CHLORAL POISONING.

By PHILIP F. ROGERS, M.D.,
MILWAUKEE, WIS.

I was called a short time ago to the bedside of a middle-aged man, and found him suffering from the effects of prolonged worry and pretty hard drinking. He was restless and sleepless, and in a mental state bordering on melancholia, having repeatedly threatened suicide. He begged me to give him sleep, and along with gradual withdrawal of whiskey and substitution therefor of strychnine and tincture of capsicum I prescribed a two-ounce mixture containing chloral hydrate gr. x. and potassium bromide gr. xv. to the drachm, instructing the attendants to give him a teaspoonful every three hours with a double dose at bedtime if he was still restless, but no more. This was on Thursday. I was not sent for again till the following Monday, when the man's peculiar actions alarmed his friends. I found the patient curled up in bed with knees and chin approximated; his extremities were cold, and he was jerking and rolling fitfully about now and then to assume a new position. Breathing was slow and stertorous with frequent prolonged, loud, grunting expirations; the pulse was slow and soft, but full; the face was ashen gray with parched mouth and lips and swollen tongue, and there was almost complete stupor. On inquiry I found that since I had last seen him he had had the bottle of sedative mixture refilled four times, and had been drinking the stuff by the half whiskey-glassful. He had slept and been wakeful by turns, but was withal in a happy mood and invited those about him to drink with him, saying it was "great stuff." Sunday night he had been in a state of happy delirium nearly all night, jumping out of bed and wandering unsteadily from room to room, but toward morning he lapsed into the stupid condition in which I found him. During all this time he had eaten heartily, but had taken little or no alcohol and scarcely any of the strychnine mixture.

On Sunday his hand had been so unsteady that he spilled considerable of the medicine on attempting to take it, and the amount so lost was about one bottleful (two ounces). During the three days, then, Friday, Saturday and Sunday, he had taken no less than eight ounces of the mixture, or six hundred and forty grains of chloral and nine hundred and sixty grains of potassium bromide! The treatment consisted in the application of heat and a hypodermic injection of strychnine gr. $\frac{1}{15}$. In a few hours the man was sitting up and chatting pleasantly, saying he did not know when he had had such a good time, although he could remember distinctly nothing of what had happened. Being upbraided for disobeying orders, he said I did not understand his constitution; that he required large doses to obtain any effect from medicines, and that what I had ordered was entirely inadequate. He praised my medicine highly and thanked me warmly for what I had done for him; but the next day and for several days thereafter he had for his companions "devils" of a deeper indigo hue than he had ever known before.

In view of the enormous quantity of the drug taken I regard his escape from death as little short of miraculous, and attribute it to the fact that he had taken food freely and had frequent movements of the bowels.

Medical Record:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

Publishers

WM. WOOD & CO., 51 Fifth Avenue.

New York, March 10, 1900.

BOARD OF CHARITIES OF THE STATE OF NEW YORK.

The thirty-third annual report of the board of charities contains much interesting matter. Never before has such activity in charitable legislation been witnessed in this State. No less than one hundred bills were introduced during the four months of the legislative session. The legislation recommended by the board to the legislature of 1900 is as follows: 1. The extension of the territory from which the New York Institution for the Blind shall receive State pupils; 2. An amendment to Section 698 of the Penal Code to prevent the sending of short-term offenders to the houses of refuge and reformatories for women. Much of the report is devoted to a history of the board's legal proceedings against the New York Society for the Prevention of Cruelty to Children.

The board reports the number and classification of beneficiaries in institutions subject to its supervision, October 1, 1899, to be as follows: Aged and friendless persons, 7,392; almshouse institution inmates, 11,251; blind in almshouses, 341; blind in other institutions, 414; deaf in almshouses, 94; deaf in other institutions, 1,548; dependent children, 31,218; disabled soldiers and sailors, 1,611; epileptics in almshouses, 316; epileptics in Craig Colony, 378; hospital patients, 8,223; idiotic and feeble-minded in almshouses, 1,153; idiotic and feeble-minded in State institutions, 1,303; juvenile offenders, 3,501; reformatory inmates (women and girls), 1,868; making a total of 70,611. The board calls attention to the urgent need of further provision for the feeble-minded and idiotic. The removal of the House of Refuge at Randall's Island from its present situation to one in the country is earnestly recommended by the board.

With regard to the Craig Colony for epileptics the report says: "The experience of the past three years is sufficient to encourage the belief that this greatest custodial effort of the State of New York will meet the anticipations of its founders. Time for gradual and carefully studied development is necessary, and it cannot consistently be expected that the complete organization and establishment of so extended an experiment can readily be effected. For success in this as in all similar enterprises a scrupulous attention to details of development and painstaking economy are essential. The number of dependent epileptics in the State reported to the board at the time the recent census was taken is 785, and the Colony expects to be able to receive 270 of this number within a comparatively short time."

The other institutions inspected were, on the whole, in a highly satisfactory condition, and it is gratifying to note that by removing children from Randall's Island and placing them at board in families the mortality has been reduced to a point far below that of the previous years.

ADULTERATION OF FOOD.

This is a matter which has within the past few years assumed a somewhat alarming phase. While granting that in many instances the dangers arising from this cause have been greatly exaggerated, and that for the most part the chemicals used in the adulteration have little harmful effect, yet at the same time this line of reasoning does not in any way justify the practice. No sane person will be found to assert that the so-called preservatives are beneficial to health; on the contrary it is certain that they are all harmful in a greater or less degree. The truth undoubtedly is that foreign substances are added for the purpose of gaining a larger profit than would be possible if the article offered for sale were what it is labelled. An individual has a right when he buys a food commodity to obtain exactly that which he requires, and this right should be protected by law. It is said, and there would seem to be no cause to doubt the truth of the statement, that the adulteration of food is carried on to a greater extent in the United States than in any country in the world. The various States are unable by their own police regulations effectually to protect their citizens from such practice. Therefore the only course to be pursued is, in the words of the memorial from the National Pure Food and Drug Congress, held in March, 1898, "to secure suitable legislation of a national character to prevent the adulteration of food, drinks, and drugs, and to secure the enforcement of such laws."

AN INQUIRY INTO THE LOCAL GOVERNMENT OF THE CITY OF NEW YORK.

A bill has been introduced into the Assembly for the purpose of authorizing the appointment of a commission to inquire into the local government of the city of New York and the charter thereof, and to suggest legislation thereon. The proposed commission, consisting of fifteen persons, is to be appointed by the governor thirty days after the bill takes effect. The powers to be placed in the hands of the commissioners will be considerable, and the result of their investigations should be for the public weal. Nothing is mentioned in the provisions of the bill as to the constitution of the commission, but the suggestion has been made that at least one physician should be included among its members. A consideration of the charter must necessarily embrace many matters connected with the public health, and it would therefore appear fitting that the medical profession should be adequately represented. There would be no necessity to make this a provision of the bill, but in the event of its becoming law the governor should be urged to appoint one or more members of the commission from among the physicians of this city. We are of the opinion that this suggestion should be acted upon both in the interests of the population of New York City at large and of the medical profession.

THE SOLUTION OF AN ECONOMIC PROBLEM.

We live in an age of fragmentary knowledge. Everybody is developing some independent line of thought, discovery, or action, but as a people we do not know what our contemporaries are doing for us until the fact-fragments are collected and digested.

One of the first books of the year will doubtless be one of the most useful and practical in the coming century, for the reason that it is the summing up of methods and theories, with a practical solution of a medico-social problem. "The Care and Treatment of Epileptics," by William Pryor Letchworth, LL.D., is a unique work. It contains a critical summary of the various methods that have been adopted for the support and the amelioration of this class of dependents.

Mr. Letchworth traces the first charitable attempts made over a century ago to relieve epileptics, down to the more efficacious and modern methods adopted in France and Germany. The Bethel colony near Bielefeld in Westphalia he describes as the most far-reaching and beneficent in its results. The colonization system for epileptics, as put into working practice there, has become the accepted model for philanthropic work among them to-day. And it was this system, as examined by Dr. Peterson, and worked up by such able men on the State Charity Commission as the late Oscar Craig and Mr. William Letchworth himself, that brought about, in New York State, the establishment of Craig Colony.

It is not the extolling of a philanthropic scheme that makes this book valuable; it is the practical discussion of site, labor, buildings, restrictions, diet, training, supervision, economics, nursing, and treatment of epileptics that illustrates what has been done in this beautiful Genesee village, with its farm lands and orchards, to make the epileptic a useful, happy member of the community, in spite of his fits. He contrasts the greater benefits of the village life as against the institution life, such as is very ably carried out in the Ohio Hospital for Epileptics at Gallipolis. He shows the practical proof of the statement so often made by Dr. Spratling, medical superintendent of Craig Colony, that "out-door work is the keystone in the arch of treatment of epilepsy." He shows how this very out-door work provides the vegetables and dairy produce which are recognized as the best diet for such patients, and how the tonic of fresh air, combined with the soporific effect of tired muscles, induces sleep and renders the long-established bromides unnecessary.

Five States in the Union, including Massachusetts, New Jersey, and Texas, have made some provision for this dependent class of unfortunates, the provisions of which Mr. Letchworth has discussde in detail. There are also many private institutions, but none seems to give such help to the individual nor renders him capable of as much self-support as the methods adopted by Craig Colony.

The chief value of Mr. Letchworth's historical sketches and descriptions of methods of work is that it is now possible for every State in the Union to establish just such a colony without the labor of breaking the ground of new ideas and untried philanthropy, and of slowly bringing public opinion and charity commissions to the sticking-point.

THE SIEGE OF LADYSMITH.

The siege of Ladysmith adds yet another page to the already long list in the history of beleaguered towns. The condition of the garrison and inhabitants of the place when relief came affords further evidence of the capacity of the human body to withstand the attacks of famine and disease, if buoyed up and stimulated by a sense of duty. In brief, here is one more instance of the influence of mind over matter.

The state of the survivors in Ladysmith is said to have been pitiable; they were reduced to eating horse and mule flesh, and the water of the Klip River, whence they derived their supply, was so contaminated by the Boers as to be almost undrinkable. The putrid water was undoubtedly the cause of the greater part of the sickness, and the question is being asked whether the shut-in force was sufficiently supplied with filters, or, if so, whether their use was strictly enforced. The contention has been put forward by many experts that water, however much it may be infected, if passed through a reliable filter will have no injurious effect upon the consumer. This is a point that up to the present has not been made altogether clear, and requires additional proof before being accepted as an undeniable fact. The campaign in South Africa should go far toward solving the problem. Probably the efficacy of even the best of filters has been overestimated, or it may be that under the "stress and storm" of siege, and owing to the well-known carelessness of soldiers, it was found impossible to insist upon the general use of this method of purifying water. At any rate irrefutable figures show that during the enforced occupation of Ladysmith by British troops, eight thousand, or more than two-thirds of the total number, passed through hospital, a goodly proportion of which we may take it were suffering from the consumption of polluted water.

The war in South Africa viewed from a medical standpoint has taught and will teach many useful lessons, not the least of which is the need of keeping up the army medical service to its proper strength. The task of making "bricks from straw" is extremely difficult, and this country as well as Great Britain has recently learned the absolute folly of a policy of unpreparedness.

News of the Week.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending March 2, 1900. February 26th.—Passed Assistant Surgeon F. W. Olcott detached from the naval recruiting rendezvous, Detroit, Mich., and ordered home and to wait orders. Assistant Surgeon J. A. Murphy ordered to the Pensacola navy yard. February 27th.—Passed Assistant Surgeon W. F. Arnold detached from the Pensacola navy yard and ordered to the naval hospital, Norfolk, Va., for treatment. Assistant Surgeon D. H. Morgan ordered home from the Asiatic station and to wait orders.

Vital Statistics of Havana.—We have received from Major John G. Davis, surgeon U.S.V., and chief sanitary officer of Havana, some interesting statistics in regard to births, marriages, and deaths in that city during the ten years ended December 31, 1899. In that period there were 40,509 births, 9,596 marriages, and 101,932 deaths, an apparent excess of 61,423 deaths over births. The death rate was heaviest during 1898, 1897, and 1896 in the order named. Of the total number of deaths during the decade 5,413 were from yellow fever, and 96,519 from other causes. Of the 40,509 births during the ten years covered by the report, 34,498 were whites, 2,248 negroes, and 3,763 mulattoes. Of the births 26,489 were legitimate and 14,020 were illegitimate. Of the marriages during the same period 9,068 were whites, 394 mulattoes, and 134 negroes.

Dr. Andrew J. McCosh, who has been suffering from septic poisoning resulting from a cut on the arm while performing an operation, is now happily convalescent.

A Leper Refused Admittance.—A young man from Barbados was recently detained by the immigration office and ordered to be returned to Bridgetown. He was the son of an official there, and himself had held a clerkship in one of the colonial government offices. A few months ago he became afflicted with a malady which several physicians who examined and treated him said required cool weather for its cure. He intended going from here to Canada.

To Abolish the Office of Coroner.—Dr. Henry has introduced in the Assembly a bill to obtain more accurate determination of the causes of death in cases of those who have died suddenly or under conditions which warrant the suspicion of crime. The bill will confer on boards of health certain duties and powers in the investigation of such deaths, and abolishes the office of coroner.

Surgeons in South Africa.—It was announced recently in Parliament that three hundred and sixty-eight regular army surgeons and one hundred and thirty-three civilian surgeons were now with the British army in South Africa, and that twenty-eight more civilians were under orders to go to the Cape. Of the other regular surgeons, three hundred and seventy-seven were at colonial stations and one hundred and eleven at home stations, in addition to one hundred and twelve retired officers who were temporarily employed on home duty. The organization of the medical staff in this war has been praised by every one competent to speak or cognizant of the facts. Even such a fuzzy old fossil as the Duke of Cambridge, who did all in his power when commander-in-chief of the army to degrade and humiliate the medical officers, has been forced to the confession that one of the few bright things of the war has been the magnificent work done by the army medical department under Surgeon-General Jameson.

Smallpox among Students.—According to a press despatch nine students of the Detroit College of Medicine are confined in the pest hospital with smallpox, and two others are at their homes in the country with what is believed to be the same disease. About two weeks ago the students dissected a negro's cadaver, shipped from the South, and among those present were the eleven now ill. The cases are all mild, as all those affected had been vaccinated in infancy. A freshman at the Sheffield Scientific School at Yale University was recently attacked with smallpox. All his associates who had been in his company recently have been revaccinated and isolated.

A New Public Hospital for Crippled Children.—The Ways and Means Committee of the Assembly has reported favorably the bill appropriating $10,000 for the establishment in New York City of the "New York State Hospital for the Care of Crippled and Deformed Children." There is to be a board of five managers, appointed by the governor.

Casualties at Ladysmith.—The following were the total casualties among the British troops during the siege of Ladysmith: Killed or died of wounds, 24 officers and 236 men; died of disease, 6 officers and 340 men; wounded, 70 officers and 520 men, exclusive of white civilians and natives.

Disinfection of the Urine in Typhoid Fever.—The New York City board of health has issued a bulletin calling attention to the fact of the frequent presence of typhoid bacilli in the urine of persons suffering from this disease, and urging upon practitioners and those in attendance upon the sick the importance of the disinfection of the urine in such cases. The best disinfectant for this purpose is carbolic acid, it is effectual, cheap, and easily obtained. Urine to which has been added one-third of its volume of a 1:20 solution of carbolic acid is thoroughly disinfected in a few minutes. The best method is to keep the urinal or bedpan partly filled with the disinfecting solution at all times. In this way any germs present in the urine are almost instantly destroyed. It is believed that careful disinfection of the urine and fæces in typhoid fever would eventually produce a sensible diminution in the number of cases of this disease occurring in New York City, and a corresponding reduction in the death rate from it.

To Shorten the Medical Course.—In response to an appeal by college presidents to admit to the second year of the medical course graduates qualified in the branches taught in the first year of the course, the Pennsylvania State Medical Council adopted the following resolution:

"*Resolved*, That in the judgment of the council, when the medical course of a literary college, as proven by the examination of the student by the medical college, covers the entire work of the first year of actual medical study, such course may be accredited by the medical college as the first year of medical study required by law."

The Plague is not yet entirely stamped out in Honolulu, three fatal cases having occurred there on February 19th. The victims were Chinese, two men and one woman.—It is reported from Texas that there have been several cases of bubonic plague on the island of Cozumel, off the coast of Yucatan.

Pennsylvania State Medical Examinations.—The next examinations by the Pennsylvania State board of medical examiners will be held from June 26th to 29th for graduates of regular medical colleges at Pittsburg and Philadelphia, for graduates of homœopathic colleges at Philadelphia, and for graduates of the Eclectic College at Harrisburg.

Fraud in Medical Examinations.—In a report presented by a committee of the Pennsylvania State medical examining-board, appointed for the purpose of investigating charges that graduates of medical colleges had obtained in advance the lists of questions used in recent examinations for the license to practise medicine, it is admitted that the questions were in the possession of some of the candidates prior to the examination in June, 1899, and the office of the public printer is suggested as the point of leakage. It is added that the percentage of candidates having prior possession of the questions was comparatively small, and that of those having the questions almost all would have passed the State examination.

The Hahnemann Monument.—A joint resolution introduced by Representative Dalzell, granting permission for the erection of a monument in honor of Samuel Hahnemann, the founder of homœopathy, has passed both houses of Congress and has been signed by the President. The committee on the library, to which this bill was referred, reported it back to the House favorably, and recommended that the chief of engineers, United States army, the chairman of the joint committee on the library, and the chairman of the monument committee select a site to build the foundation. The monument will be of gray granite with statue and bas-reliefs of bronze. It will be an elliptical exedra with a sitting statue of Hahnemann on a pedestal in the centre. It is expected that the corner-stone will be laid on April 11th, the one hundred and forty-fifth anniversary of Hahnemann's birth.

Tenement-House Reform.—A joint bill has been introduced into the New York Senate and Assembly to effect a reform in the laws governing tenement houses. The bill authorizes the governor to appoint a commission to inquire into the New York City tenement question, and to report to the next legislature a code of tenement-house laws.

Philadelphia County Medical Society.—At a stated meeting held on February 28th, Dr. Andrew J. Downes read a paper entitled "Siphonage of the Partitioned Bladder," with the demonstration of a new instrument designated "the separate urine siphon." Dr. J. Madison Taylor presented the report of the committee to secure a pay hospital for contagious diseases, and a resolution was adopted favoring the establishment of such an institution. Dr. George C. Stout read a paper on "Some Diseases in Children."

A New French Hospital.—The board of managers of the French Benevolent Society has decided to erect a new hospital building. The present hospital of the society was established in 1881. It contains seventy beds and twelve private rooms. The capacity of the building which it is proposed to erect will be one hundred and fifty beds and twenty-five private rooms, besides sun parlors for convalescents and the inevitable and unneeded dispensary.

The New Orleans Polyclinic.—A report being in circulation that this school has been closed on account of the prevalence of smallpox in New Orleans, Dr. Isadore Dyer writes that the smallpox situation in the city has at no time justified the apprehensions of any intending visitors. He says that the Polyclinic will not close until the end of the regular term in May.

Hospital Corps of the National Guard of the State of New York.—Assemblyman Cotton has introduced a bill into the legislature amending the military code by providing that there shall be attached to each regiment in the National Guard a pharmacist who is to rank as first lieutenant; two hospital stewards instead of one, and three if the regiment consists of more than ten companies. The bill also increases the number of members of a regimental hospital corps from thirteen to twenty-five.

Obituary Notes.—Dr. Christopher Prince died on March 4th, at his home in Irvington-on-Hudson, from pneumonia. He was born in Brooklyn in 1823. He studied medicine under Dr. Willard Parker, and was graduated from the College of Physicians and Surgeons in this city in the class of 1845. For some years he lived at Fort Hamilton. He subsequently moved to New York, where in 1872 he was appointed police surgeon, which place he resigned to accept the surgeonship of the fire department. A few years later he moved to Irvington. He was a member of the Academy of Medicine, the County Medical Society, and the Pathological Society, and was for some years chairman of the obstetrical section of the Academy.

Dr. Clarence Edwin Beebe, a well-known homœopathic practitioner of this city, died March 1st. He was a graduate in arts of Yale and in medicine of the medical department of the New York University in the class of 1873. He was assistant surgeon of the Seventh Regiment Veteran Corps.

Progress of Medical Science.

Medical News, March 3, 1900.

A New and Improved Method of Entering the Abdominal Cavity in the Ileocæcal Region, with Special Reference to the Removal of the Vermiform Appendix.—George R. Fowler states that the incision in all cases of appendicitis should be so planned as to include removal of the appendix; thus there must be free access to the base of that organ. Attempts to fix arbitrarily the exact location of the base of the appendix in its relation to the anterior abdominal wall have proved futile on account of the varying anatomical relations in different individuals. Fowler's favorite incision is so planned that its centre strikes a point corresponding to the intersection of a line extending from one anterior superior spinous process of the ilium to the other, with a vertical line drawn half-way between the median line and the right anterior superior spine. He then describes his method of procedure in detail, summing up its advantages as follows: Ready access to the ileocæcal region and ample room for manipulation; weakening of the abdominal wall and liability to surgical hernia are reduced to a minimum by (*a*) incising the necessary structures so that an immediate, firm, and permanent union is secured, and (*b*) avoiding injury to the vessels and nerves of the involved parts.

Notes on Plague.—H. E. Deane draws the following lessons from Indian experience of the plague: The fact is emphasized that compulsory measures have failed to have the desired repressive effect on the disease, because the populace have been dead against them and the authorities. The people distrust the possible stringencies that might be imposed on them in an epidemic of more formidable proportions. Occidentals dislike to have their sick removed to hospitals and their homes disturbed. They suppress information concerning the disease as far as possible. Even the medical practitioners afford little or no help in this way, for fear of losing practice. The whole question is a medico-political one in which medicine has to be subservient to policy. Deane believes that hygienic precautionary measures will do more to stamp out the plague than all the bayonets of the British army.

Status of Medical Practice in Puerto Rico.—George G. Groff gives the essential points in the order regulating the practice of medicine, pharmacy, and dentistry in Puerto Rico. An examining committee of three physicians, two pharmacists, and one dentist is appointed to conduct examinations under rules made by the superior board of health. The members of this committee must all be of ten years' standing and recognized professional ability, and must speak English. The superior board of health appoints the president and secretary of this committee. The examinations are all written and the papers submitted to the board of health, by whom licenses are issued to the successful candidates. Examination fees are: For physicians and surgeons, $25; pharmacists, $25; dentists, $25; practicantes, $15; professional nurses, $10; midwives, $5. Persons who violate the order may be punished by both fine and imprisonment.

The Xiphopages, Rosalina and Maria.—Alvaro Ramos describes his operation which he undertook to separate these wonderful twins. All possible precautions were taken in order that if the desired result could not be attained there should be no disastrous effect. Unfortunately the parenchyma of the two livers was continuous, and further steps in the separation were abandoned. The twins made a good recovery.

A Case of Salivary Calculus from the Submaxillary Gland.—S. H. Dessau reports this case in which the condition suggested some slight suspicion of Ludwig's angina. Suppuration and spontaneous rupture occurred, followed by recovery. The calculus was passed from Wharton's duct and measured eleven-sixteenths by twelve-sixteenths of an inch.

Again the Question of Cancer.—By Roswell Park. See MEDICAL RECORD, vol. lvii., p. 212.

Journal of the Amer. Med. Association, March 3, 1900.

Chancre of the Lip in a Child Seven Months Old.—L. Duncan Bulkley says that while extragenital chancres innocently acquired are not so very rare, instances of their occurrence at the early age of seven months are seldom seen, this being the youngest subject in whom he has seen it among nearly two hundred cases of extragenital chancre coming under his observation. Careful questioning of the mother failed to reveal any source of the infection. The parents. however, were from Finland, where syphilis is very common, and the child was bottle-fed. It is more than probable, therefore, the writer thinks, that some friend while caring for the child infected the nipple of the bottle when testing the food. This is a trick common among nurses, who then place the nipple in the child's mouth without washing it.

Legislative Problems in the Regulation of Marriages.—C. W. Parker considers the obstacles in the way of legislation regulating marriage. He then suggests as a partial remedy, until education shall have blazed a path for more stringent measures, a bill which, while calling for the examination of men, shall exempt women, thus doing away with what he calls "the sentimental objection," which bill shall also be drawn so as only to include those with tuberculosis when actually developed, dipsomania when positively proved, and syphilis in all its stages, together with actual imbecility.

Can the State Suppress Genito-Urinary Diseases?—Ferd. C. Valentine answers this question by the following summary: (1) Illegitimate relations between sexes have always existed; (2) moralists, theological or lay, could never induce the suppression of vice; (3) physicians know that men who have suffered most intensely from genito-urinary disease will expose themselves to new infection even long before they are cured. The writer sees the only remedy in the proper enlightenment of humanity, especially the frank education of the young in these matters.

Restriction of Marriage for the Prevention of Communicable Diseases.—Albert H. Burr instances the Creed bill, passed by the senate of South Dakota, as being a step in the right direction. He says that similar bills have been presented or are ready for presentation in several other States, and he confidently expects to see State after State follow this lead, as the public become sufficiently educated to realize its importance.

Restrictive Marriage Legislation from the Standpoint of the Wife, Mother, and Home.—Mrs. Alice Lee Moqué asks: "May it not be that surgical science shall be the means of giving humanity the panacea for the crime committed against progeny by the criminal and degenerate classes? The writer refers to a method for effecting the sterilization of women as practised by Professor Spenelli, of Turin.

The Legal Restriction of Marriage for the Prevention of Pauperism, Crime, and Mental Diseases.—Albert H. Burr thinks that the time is not yet ripe for legislation in this matter, and will not be until the laity have been educated by the medical profession up to the point of demanding for themselves the necessary enactments.

Simple Device for Rapid Hypodermoclysis in Combating Shock.—Evan O'Neill Kane says the objection to hypodermoclysis has been that it is too slow in action. To obviate this he has devised an apparatus with which four or more needles may furnish fluid to the tissues at the same time, from a single receptacle.

Two Practical Points in the Care of the Tuberculous.—William Porter urges the importance of two indications in tuberculosis—relief of heart weakness and of constipation. He believes these conditions to be a part of the direct progress of the disease, and complications of no little gravity.

A Clinical Study of Four Hundred and Fifty Cases of Scarlet Fever.—Annie Sturges Daniel presents a detailed study of scarlet fever occurring in children under twelve years old in the tenement houses of the East Side in New York City.

Ureteral Calculus.—Howard A. Kelly reports a case of ureteral calculus in which the diagnosis was made by means of the wax-tipped bougie. The calculus escaped per vias naturales after forcible dilatation of the ureteral orifice.

Value of Formaldehyde in the Disinfection of Buildings, Rooms, and Cars.—John E. Owens reports gratifying results from experiments made with the German forty-per-cent. solution of formaldehyde.

Two Hundred and Twenty Cases of Hemorrhoids.—These cases, reported by Joseph B. Bacon, were all successfully operated on by the ligature method, with only one complication.

New York Medical Journal, March 3, 1900.

Rheumatic Gout.—B. C. Loveland considers this affection worthy of being called a painless rheumatism, and studies the clinical aspects of the disease. Illustrations and radiographs are given of cases which have come under his own observation. Treatment is comprised under the headings of dietary, hygiene, and hydrotherapy, and medicinal. He finds the most useful remedies to be the salicylate and benzoate of sodium and the iodide of potassium. It may be necessary to study each individual case for some time before finding the alkali which will give the best effects.

A Case of Ossification of the Uterus.—C. Jeff Miller reports the case occurring in a girl aged sixteen years, with absence of the vagina, and in the space normally the site of the uterus and appendages was a mass which was removed by abdominal incision, and which proved to be composed of true compact bone. No trace of ovarian or tubal structure could be found.

Typhoid Fever.—C. E. Page gives some general observations on the subject and describes what he considers to be the physiological treatment including physiological diet. He advocates the Brand bath, temporary fasting for diarrhœa, and free use of water internally. He considers that college teaching is very imperfect in the matter of fever therapy.

Another Accommodation of the Eye.—N. B. Jenkins calls attention to the power manifested by the eye in "adapting itself to badly fitting glasses." This "other accommodation" of the eye is the chief stock in trade of the wandering spectacle expert, and is the sheet anchor of unscientific refraction methods.

A Partial Study of a Child Presenting Multiple Deformities.—G. R. Elliott gives illustrations of a case occurring in the practice of J. Fraenkel and B. Onuf. The deformities were double drop-wrist, double drop-foot, subluxation of the left hip joint, and a forward dislocation of the right radius.

Thirty-two Cases of Typhoid Fever without a Death.—J. C. Crist advocates in his treatment of the disease bathing, milk with lime-water (but if this disagrees, he substitutes soft-boiled eggs, meat broths, and soups), and carbonate of guaiacol for the intestinal symptoms.

Primary Hemorrhage following Amygdalotomy.—A case in a woman aged twenty-six years is reported by G. B. Hope. Bleeding was finally checked by application of the galvano-cautery after the failure of cocaine, antipyrin, cold, and hydrogen peroxide.

Some Therapeutic Notes.—Philip Zenner commends the use of apomorphine in tachycardia and cacodylic acid in anæmia.

Boston Medical and Surgical Journal, March 1, 1900.

Psychology and Heredity.—Robert MacDougall, in concluding his article from the previous number, compares the Spencerian and Weismannian theories, and says that the moral problem is absolutely different according as we hold to one or the other. According to the first the effects of use and disuse are inherited, and the cumulative results of right thinking and right living in the end convert bad stock into good stock. Restraint, discipline, the conformance to a higher life are fundamentally hopeful. Under the Weissman concept there is no hope—the bad stock is no more got rid of by discipline and culture than are the impurities of a river by filtration of the water on the part of those living below the source of pollution.

The Relative Humidity of Our Houses in Winter.—Robert DeC. Ward says that the present means of heating our houses are wretchedly inadequate from the point of view of supplying sufficient moisture. The relative humidity of the air coming from an ordinary furnace may be somewhat increased by increasing the size or the number of the evaporating pans in the furnace, or by placing pans of water on, or better still within, the registers. Dr. H. J. Barnes has found that with a relative humidity raised from thirty-one per cent. to fifty-three per cent., his office is comfortable at a temperature of about 65°, whereas before a temperature of 70° to 71° was required.

Vivisection in Harvard Medical School.—James J. Putnam writes a strong paper in denial of charges brought against physiological investigations, meeting the various accusations and successfully disposing of them, showing that they are made in ignorance of what is really done in vivisections, of the actions of drugs used, and of the value of results obtained. He pleads with investigators, physicians and laymen, to oppose the bill to restrict experimentation on living animals, since the object of vivisection is to diminish pain in both human beings and animals by increasing our knowledge of the conditions which underlie health and disease.

Stricture of the Ureter a Possible Result of Laceration of the Cervix Uteri, and Uretero-Vaginal Fistula a Result of Trachelorrhaphy.—E. C. Dudley describes an interesting case.

Perinephritic Abscess Involving the Appendix.—Hugh Williams describes a case in which the appendix was probably secondarily involved. Recovery followed operation.

Philadelphia Medical Journal, March 3, 1900.

Cultivation of the Typhoid Bacillus from Rose Spots.—Mark W. Richardson reports the results of six cases in which a bacteriological culture examination was made of the exanthem in typhoid fever. In five of these cases the bacilli were found from two to twelve days (average about six) before the Widal reaction was obtained. The writer believes, therefore, that the method may be of diagnostic service.

Exploratory Laparotomy under Local Anæsthesia for Acute Abdominal Symptoms Occurring in the Course of Typhoid Fever.—Harvey Cushing reports five cases of this description, in one of which recovery occurred, and discusses the advantage of cocaine anæsthesia in such operations.

Typhoid Fever in New Orleans.—P. E. Archinard discusses the causes of the prevalence of the disease in this city, and gives a summary of twenty-two cases occurring in the practice of several physicians. Like all other germ-diseases in New Orleans, he says, typhoid fever is there of a decidedly benign type.

Monocular Diplopia in Typhoid Fever.—Edward B. Heckel reports a case of typhoid fever in which the diagnosis was not made because of the irregularity of the symptoms, one of which was a monocular diplopia lasting two days. Subsequently the patient relapsed into a typical typhoid condition.

Three Cases of General Convulsions in Typhoid Fever.—Thomas Ash Clayton reports three cases of this rare complication, two of which appeared to be due to the action of the toxins on the nervous centres, the other possibly being a case of intracranial thrombosis or hemorrhage.

The Therapeutic Use of Water.—George P. Sprague discourages a resort to hydrotherapy by those unable to judge of its value by its physiological effects. But when its physiological effects are kept in mind the scientific application of water is a valuable means of combating disease.

Brand Treatment.—J. C. Wilson and J. L. Salinger present a summary of 1,904 cases of typhoid fever treated during the past ten years by systematic cold bathing combined with the administration of drugs as indicated. The mortality was 7.5 per cent.

The Nervous System in Typhoid Fever.—Edward E. Mayer reports several cases in which the nervous symptoms were especially marked. He says that typhoid fever is as much an infectious disease of the nervous system as of the abdominal organs.

A Case of Suspected Typhoid Fever Shown to be Acute Catarrhal Otitis Media without Pain.—Charles H. Burnett reports a case in which paracentesis of the drum membrane was followed by a speedy subsidence of the fever and delirium.

The Diagnosis of Perforation in Typhoid Fever.—Alexander McPhedran says this accident often occurs unaccompanied by strong symptoms. Persistent pain is perhaps the most constant sign in these marked cases.

Surgical Sequelæ of Typhoid Fever.—Under this head Martin B. Tinker reports cases of œsophageal stricture, hip-joint ankylosis, costal osteomyelitis, and spondylo-arthritis.

Typhoid Fever Complicated by Meningitis.—H. M. Fischer reports a case in which the bacillus typhosis was found in cultures made from beneath the cerebellar meninges.

Water-Borne Diseases.—E. G. Matson advocates sand filtration of a city water supply as the only practical method of purification which has stood the test of experience.

The Treatment of Typhoid Fever.—Frank Billings advocates the cold bath with friction, the effect of which is to increase enormously the elimination of toxins.

The Ocular Complications of Typhoid Fever.—G. E. de Schweinitz discusses affections of the eye which may occur during or after an attack of this disease.

Observations on the Gruber-Widal Reaction in Typhoid Fever.—By Aloysius O. J. Kelly and Alexander A. Uhle. See Medical Record, vol. lvii., p. 193.

The Duty of the Physician in Preventing the Dissemination of Typhoid Fever.—By Thomas G. Ashton. See Medical Record, vol. lvii., p. 193.

The Value of Clinical Laboratory Methods in the Diagnosis of Typhoid Fever.—By J. H. Musser. See Medical Record, vol. lvii., p. 193.

Preventive Inoculation and Serum Therapy of Typhoid Fever.—By Joseph McFarland. See Medical Record, vol. lvii., p. 193.

The Examination of Urine for Typhoid Bacilli.—By Norman B. Gwyn. See Medical Record, vol. lvii., p. 193.

British Medical Journal, February 17 and 24, 1900.

A Modification of the Operation of Inguinal Colotomy.—In this operation, described by R. Cozens Bailey, after the abdomen had been opened and a loop of sigmoid flexure drawn out in the usual way, the proximal arm of the U-shaped sigmoid loop was then stitched all round to the edges of the incision in the external oblique muscle by a row of sutures which penetrated the external coats of the bowel only. A second incision a little over one inch in length was then made, parallel with the first and about two inches below it. This, which was placed just above Poupart's ligament, exposed the surface of the external oblique. The band of skin and subcutaneous tissue between the two incisions was next freed from the subjacent structures with the handle of the scalpel, and the loop of intestine drawn out through the lower wound, where it was subsequently kept in position by a glass rod passed through the mesentery. The upper skin wound was closed. The object of the operation as described was to allow the pad to make pressure upon a portion of the length of the wall of the viscus as well as upon the opening itself, and thus to obtain more efficient control, as in Frank's method of performing gastrostomy.

Notes on Some Cases of Gunshot Wounds from South Africa.—These cases, reported by William Dick, include wounds of the head, neck, and chest, and abdomen. They were mostly caused by Mauser bullets, and none of them received any operative interference. The author says it must be concluded from these cases that Mauser bullets do not carry with them septic infective material. The manner in which these wounds heal is held to be matter for future investigation—possibly, the wounds being small, extravasation is prevented by contraction, this contraction being rapidly followed by plastic effusion, resulting in permanent occlusion of the openings. Perforations of the bones seem to be accompanied by little or no fissuring, and heal as rapidly as wounds of the soft parts. Perforations of the lungs also heal quickly and give rise to very few acute symptoms.

A Case of Bullet Wounds of the Chest.—F. A. Saw reports a case of wound by a Mauser bullet. From careful measurements of the wounds of entrance and exit it was found that both lungs must have been traversed by the bullet, though its exact course and how the large structures in front of the vertebral column escaped could not be explained. The symptoms—temporary sensations of paralysis of the limbs, followed by retention of urine—would suggest that the bullet grazed the body of a vertebra. Considerable pain was suffered at the point of the right shoulder, which is generally associated with some lesion of the liver. The patient made a rapid recovery, was up in two weeks, and now, a month from the date of injury, is practically well save for a little dyspnœa on exertion and slight pain on taking a deep inspiration.

Twin Pregnancy with Central Placenta Prævia.—This case occurred in the practice of H. Oliphant Nicholson. The patient was successfully delivered and appeared to be rallying, when, on making a movement to turn in bed, she suddenly expired, about six hours after the termination of the labor. The author points out that the risk to the mother must be much more grave when this condition exists with a twin pregnancy, because it would not always be possible to separate the placenta entirely, thus giving the patient time to react from the effects of hemorrhage before emptying the uterus.

An Analytical Account of Fifty-seven Cases of Puerperal Infection.—In giving an account of these cases the author, W. Edgar Macharg, has not attempted classification, simply arranging them according to result, as fatal or non-fatal. The writer has attempted to bring into relation and prominence the chief points of interest in the total number of cases, at the same time giving particular attention to such as came to post-mortem examination. He hopes that the results may be found of value as being founded on a consecutive series in the practice of one observer.

A Case of Placenta Prævia and Rupture of the Uterus.—This case, reported by James Pearse, is interesting as having ended in recovery with practically no treatment. In order that union might not be disturbed the bowels were kept locked for a week, and during this time douching was avoided for the same reason. The author says that while laparotomy is undoubtedly the ideal treatment for this complication, such cases as the above serve to prove that even when this is impossible the outlook is by no means hopeless.

On the Use of Antistreptococcus Serum in Puerperal Septicæmia and Erysipelas.—Alex J. Anderson reports three cases, one of puerperal septicæmia and two of erysipelas, in which, after trying the older methods for a time, he used the serum as a last resource with excellent results. The author thinks the effects of the serum should be watched from hour to hour, day and night, on account of its depressing effect on the circulation, which lasts several days after the injections have been stopped.

Frequent Dislocation of the Right Shoulder.—P. O'Connell reports the case of a stout, well-built man, with large, powerful shoulder muscles, who constantly dislocates the right shoulder-joint. If he throws his hand above his head, or if he receives a slight blow on the shoulder, the head of the humerus slips, sometimes into the axilla, sometimes under the pectoral muscles. In one instance after the patient had flung his arm about in drunken sleep, spontaneous reduction took place.

Report on Three Cases of Gunshot Wound.—A. P. Blenkinsop reports that these three cases of self-inflicted gunshot wounds demonstrate the effects of small-calibre bullets and cordite ammunition, which effects are markedly different from those produced by the older form of rifle. Their chief interest from a medico-legal point of view rests in the fact that there was no scorching or tattooing of the tissues, although in each case the rifle must have been held very close to, if not touching, the skin.

Penetrating Wound of the Bladder and Rectum from the Buttock.—In this case, reported by J. R. Dodd, the wound of the buttock was opened up into the rectum as in the operation for fistula; the catheter was tied into the bladder, and the usual measures were taken for checking hemorrhage, which, however, continued for several days. With the exception of a severe attack of epididymitis in the left testicle, the patient made an uninterrupted recovery.

A Case of Exploratory Operation for Dilatation of the Stomach.—Ernest A. T. Steele thinks that the patient in this case would have recovered if the operation could have been undertaken before she was worn out with the constant retching. As it was, the retching ceased after the operation, and there was no pain, but a slight diarrhœa occurred and seemed to turn the scale, and the patient died suddenly with symptoms of cardiac failure.

The Bromide Sleep.—In this case, reported by Frank C. Ford, an epileptic lad, aged sixteen years, took nearly two ounces of potassium bromide in forty-eight hours. Although the stupor was marked, the writer was impressed with the comparatively slight effect of so large a dose, and he infers that manifestation of bromism depends rather on individual idiosyncrasy than on the quantity of drug taken.

A Case in which a Pulmonary Abscess was Successfully Drained.—Charles A. Morton reports a case in which the patient was expectorating about half a pint of fetid pus a day. There was an area of dulness at the right base posteriorly, and the exploring needle revealed the presence of pus. An incision was made and a drainage tube inserted into the suppurating cavity. The man made a good recovery.

Double Monster; Thoracopagus, Single Heart.—De Vere Condon describes this monster, which had two complete male bodies joined laterally from axilla to hip. An interesting point about the case is that the right child was extremely thin and emaciated, while the left child was plump. The latter is said to have lived for half an hour and the other to have been born dead.

When is Cancer Cured?—W. H. Jalland notes this case as throwing an interesting light upon what is called the "time limit." The writer removed a scirrhous growth from the axilla of a patient. Nine years and two months after he operated again, removing a lump from the site of the old cicatrix, together with the breast to which it was attached.

Fracture of Both Clavicles.—Another case of this rare accident is reported by Thomas Milne. In this case a shunter was caught by the shoulders between the buffers of two gently colliding wagons, the force seeming just sufficient to snap the clavicles, and nothing more.

Foreign Body in the Male Urethra.—Horace Wilson tells of a lady's bonnet pin passed by a drunken sailor up his urethra. Under an anæsthetic the object was recaptured, when the patient immediately rejoined his ship, feeling no subsequent inconvenience.

An Address on Medical Practice in European Countries.—Thomas Kilner Clarke summarizes the requirements for medical practice in different countries on the continent.

A Case of Puerperal Septicæmia.—In this case, reported by H. W. Webber, a favorable result was obtained from one injection of antistreptococcus serum.

Organization of Aseptic Operations and Some of the Causes of Failure.—An address delivered before the Leamington Medical Society, by C. B. Lockwood.

The Anatomy and Pathology of the Rarer Forms of Hernia.—By B. G. A. Moynihan. See MEDICAL RECORD, vol. lvii., page 421.

Recent Legislation in Relation to the Medical Profession.—An address by Fletcher Beach.

The Rôle of the Municipality in Public Hygiene.—An address by Sir Charles A. Cameron.

The Lancet, February 17 and 24, 1900.

On the Restoration of Co-ordinated Movements after Nerve Section.—R. Kennedy concludes as the result of experiments that after section and immediate coaptation of a nerve, restoration of conductivity and of voluntary function may be effected in a few days. This may be the result of regeneration of young nerve-fibres in the peripheral segment. Voluntary co-ordinated movements are regained, whether the two ends of the divided nerve are united as accurately as possible, or twisted so that non-corresponding ends of the nerve-fibres are brought into contact. In the latter case it is doubtful whether the restoration of function is due to the re-establishment of the old paths by decussation in the nerve cicatrix or to the reunion of ends of nerve-fibres which do not correspond but which happen to be brought into apposition. In suturing a divided nerve, therefore, the simple approximation of the two ends, no matter in what relationship, is all that is required.

A Case of Interstitial Fibroid Tumor Sloughing "en Masse," and Some Other Cases of Fibroid Tumors of the Uterus.—Arthur H. N. Lewers reports the following cases: suppurating ovarian tumor and uterine fibroids (ovariotomy was done and the fibroid markedly diminished in size); a case of abdominal hysterectomy with intraperitoneal treatment of stump; large abdominal tumor composed of subperitoneal fibroids (one of the latter had undergone cystic degeneration with formation of puriform fluid); subperitoneal fibroid complicating pregnancy—expectant treatment, normal labor; submucous fibroid causing hemorrhages—dilatation, enucleation, recovery (two cases); subperitoneal fibroid with adhesion to gut, left hydrosalpinx—removal of both; also the case named in the title.

A Brief Review of Our Knowledge Concerning Backward Displacements of the Pelvic Organs.—F. H. Wiggin believes that these conditions are largely unnecessary and due to preventable causes. Growing girls should be properly instructed by their mothers about mode of life, use of suitable clothing, passing urine at proper intervals, dangers of falls and of lifting heavy weights. Damage at parturition requires immediate repair. A modified rest cure should be instituted immediately after confinement, and the patient should in all cases visit the physician three months after confinement for further examination.

Measles in a Patient Aged Eighteen Years Complicated with Meningitis and Spinal Myelitis; Recovery.—A case is related by E. F. Eliot. The patient on the fourth day after appearance of the rash suddenly developed convulsions, epileptiform in character, which were referred either to toxic poisoning from measles, or to cessation of the menses, or to a general neurotic condition. The subsequent course of the case led to the diagnosis named in the title. The entire duration of the sickness was two months.

An Anomalous Case of Continued Fever with Abscesses of the Liver.—J. G. McNaught describes the history of a gunner in the artillery service, a man aged twenty-four years, who for a period of sixteen days gave symptoms of enteric fever with bowel hemorrhages. Five abscesses were found in the liver. Cultures from the spleen gave a bacillus somewhat resembling the bacillus coli and a coccus which was probably the streptococcus pyogenes.

A Successful Case of Cœliotomy for Intestinal Obstruction due to Persistent Meckel's Diverticulum.—A case occurring in a girl aged nine years is reported by C. A. Morton. The symptoms of onset suggested appendicitis. A portion of the small gut was found distended, but on tracing an empty coil of the bowel it was found that the constricting ring into which the gut had slipped was formed by a persistent Meckel's diverticulum.

Ocular Phenomena Associated with Cheyne-Stokes Respiration.—G. Y. Eales noticed in a man, aged sixty-one years, with cardiac valvular trouble, Cheyne-Stokes respiration, observing that during the interval of the series of respirations both pupils remained stationary and somewhat contracted, but as a new cycle came on they both gradually became widely dilated and so remained during the height of the cycle.

A Hepatic Mucoid Cyst.—W. C. McDonnell reports such a case in a man aged fifty-three years, suffering for some time with intermittent attacks of sudden epigastric pain. The cyst was located on the upper mid-surface of the liver, and contained a jelly-like mass of apple-green color, specific gravity 1.029, composed chiefly of mucin.

Topographical Relations of the Brain, the Frontal and Maxillary Sinuses, and the Venous Sinuses of the Dura Mater to the Walls of the Skull.—P. Regnier and J. Glover give an account of their researches, in which radiographic methods were applied to the investigation of the anatomy of the skull and face.

Epistaxis from the Ethmoidal Veins.—Four cases are reported by A. Brown Kelly. Epistaxis from the anterior ethmoidal vessels is controlled by firm packing between the septum and the anterior half of the middle turbinate, the strip of gauze reaching as near as possible to the roof of the nose.

The Anatomy and Pathology of the Rarer Forms of Hernia.—B. G. A. Moynihan discusses, in the first of the Arris and Gale lectures delivered before the Royal College of Surgeons, the anatomy and pathology of bilocular hernia, including inguinc- and cruro-properitoneal and intestinal hernia.

Hemiatrophy of the Tongue.—The case related by L. A. Parry was that of a man aged fifty years. The condition was referred to injury (possibly due to a previous fracture at the base of the skull) of the hypoglossal nerve in its passage through the anterior condyloid foramen.

Large Doses of Carbolic Acid in Equine Tetanus.—F. E. Place has injected in this disease as much as a drachm dose of the acid (B. P.), and has so used thirty-six drachms in eighty-four hours. The neighborhood of the neck and shoulders is chosen as the site of injection.

Two Cases of Pulsus Paradoxus.—John Hay describes with tracings two cases of the condition occurring in dyspnœa from bronchitis in a child, and in pleurisy and pericarditis (both with effusion) in an adult.

Diphtheria of the Conjunctiva.—S. Stevenson relates a case. He believes that a bacteriological examination will show the true diphtheritic nature of about two per cent. of all cases of ophthalmia.

Tuberculous Disease of the Kidney; its Etiology, Pathology, and Surgical Treatment.—By D. Newman. A continued article.

The Anatomy and Pathology of the Eye.—By E. Treacher Collins. The Erasmus Wilson lectures.

Medical Press and Circular, Feb. 14 and 21, 1900.

The Risks of Unoperated Uterine Fibromata.—E. Stanmore Bishop says the dangers may be divided into two classes: those directly due to the presence of the growth itself; secondly, those which render dangerous an operation undertaken late. All these are avoidable and unnecessary if surgical aid is obtained sufficiently early. There are five inherent dangers: Death from hemorrhage, from sepsis, from pressure upon important organs, death during or after pregnancy, death from cardiac degeneration owing to persistent loss of blood. The operation for fibroid has the advantage over that for malignant disease, that there is no recurrence for the patient to fear. There should be less waiting for the menopause.

A Case of Inward Displacement of the Lower Epiphysis of the Humerus.—D'Arcy Power describes a case of this injury in which the arm was in a state of cubitus varus, the long axis being directed inward at the elbow. The case belongs to a very obscure class, becoming better known by application of the Roentgen rays, which showed that separation of the lower epiphysis of the humerus had been subperiosteal. The external condyle had lost its cartilaginous covering, and the epiphysis seemed fixed in its new position by ossification of the periosteum.

Note on a Case of Loose Body in the Knee-Joint.—R. G. Patteson reports a synovitis with locking of the joint, preceded by occasional pains for six weeks and the feeling of something loose in the joint. A loose body was located and cut down upon, and when extracted appeared to consist of equal proportions of bone and cartilage. It was supposed to be derived from an outgrowth in the course of chronic rheumatic arthritis.

Chronic Total Inversion of the Uterus.—F. W. Ramsay reports a completely inverted uterus covered with phosphates. The base of the bladder was completely gone, exposing the fundus, the edges being composed of dense cicatricial tissue. The womb was removed and an operation done to close the fistula. The patient was able to do all her work and retain her urine for three hours.

Uterine Myoma Associated with Temporary Glycosuria and Umbilical Hernia.—Arthur E. Giles reports a case in which subperitoneal hysterectomy was done in a woman whose glycosuria was functional and due to nervous apprehension of the operation. Sugar persisted after the operation for a week. Cure of both conditions resulted.

Distended Pyosalpinx.—F. A. Purcell records a case of distended pyosalpinx of the right side, the opposite tube being distended and thickened. The uterus was removed by the subperitoneal method, with recovery.

Instruction in Obstetrics and Gynæcology.—Abstract of presidential address of W. J. Smyly delivered before the British Gynæcological Society, February 8, 1900.

The Dilatations and Diverticula of the Œsophagus.—A continued article by John Knott.

Treatment of Pleurisy.—A clinical lecture by Prof. G. Debove.

Berliner klinische Wochenschrift, February 12, 1900.

Epidemiology and Prophylaxis of Malaria from Most Recent Etiological Standpoints.—A. Celli believes that cases of malaria should be isolated in the same manner as are infectious diseases. He believes in the mosquito theory of causation, and advises the immediate removal of the patient from the place in which he contracted the disease. He does not think that we possess at the present time any means which can prevent the ravages of this insect, and the ideal place for the patient is a sanatorium on high ground with plenty of fresh air. The patient is not to be allowed to revisit the place of infection until examination of his blood and spleen shows absence of malarial organisms.

Polyarthritis Chronica Villosa and Arthritis Deformans.—M. Schueller concludes a lengthy article upon this subject. Arthritis develops often spontaneously without any preceding joint inflammations. The possibility of a bacterial origin is still uncertain. More likely a disturbance of nutrition lies at the bottom of the malady. Most of the patients suffer from constipation and flatulence, and an interference with the elimination of lime salts from the body. An essential point in treatment is to provide a dietary which is poor in this particular chemical element, and to pay special attention to the action of the bodily emunctories.

The Origin of Dermoid Cysts.—S. W. Bandler regards these structures as due to the development in abnormal situations of certain embryonal cells and organs, which in this new situation elaborate themselves in exactly the same way as if they were normally situated. Such abnormal development begins at a time when the loss of cell elements from their normal site is made good by the development of other similar cells at the original site. Hence, in spite of the abnormal development, we have the bodily organism coming to full maturity.

Experimental Researches on Bleeding in Uræmia.—P. F. Richter finds that in rabbits slow and gradually progressive renal insufficiency from increasing doses of renal poison is not changed by bleeding. There is no essential lessening of osmotic pressure in cases of sudden increased concentration of the blood through bleeding either with or without saline infusion. He would not, however, deny that clinical observation in man emphasizes the fact that bleeding in uræmic states is of benefit.

Nature's Methods of Protecting the Organism against Infection.—By P. Baumgarten. A continued article.

Auto-Intoxication.—By C. A. Ewald. A continued article.

Wiener klinische Wochenschrift, February 8, 1900.

The Influence of Thyroid Extract on the Circulation and Respiration, besides an Addition Concerning the Relations between Iodothyrin and Sodium Iodide, or Atropine.—Béla v. Feryvessy, from his experiments on rabbits, says that the influence of thyroid extract on respiration was not uniform. Often the intravenous injections were followed by no changes. Sometimes an acceleration resulted. The characteristic influence on circulation was a lowering of blood pressure. From his observations he cannot confirm the statements respecting the antagonistic influence of iodothyrin to sodium iodide or atropine. He thinks that the apparently positive results in regard to this have been deceptive on account of the transitory influence of sodium iodide and atropine.

Opinions of the Medical Faculty in Vienna. Murder Committed by an Intoxicated, Ethically Depraved Individual; Alleged Acute Intoxication and Somnolence.—V. Wagner relates this case and gives the questions asked by the court: Did this man commit this deed while entirely robbed of his reason, or was it during a period of insanity which alternated with a normal mental state? The answer was that he was ethically defective as well as being intoxicated at the time. The criminal was condemned for manslaughter and sentenced to eight years' imprisonment.

Disturbances of the Vasomotor Function and Sensibility after Peripheral Traumatic Facial Paralysis.—Carl Biehl reports a case and considers that it proves what Frankl-Hochwart has maintained, that the facial nerve contains also both sensory and vasomotor fibres.

Münchener medicinische Wochenschrift, Feb. 6, 1900.

The Reaction of Leucocytes to the Tincture of Guaiac.—Kurt Brandenburg believes that the reaction of pus to tincture of guaiac deserves a more extensive use as a convenient reagent for pus in the urine and other excreta. It is often advisable to filter the urine and use the filter for the reaction on account of the many reducing substances in the urine which hinder the appearance of the blue coloration. In like manner, by filtering off a few drops of blood dissolved in water, in cases of leukæmia, the reaction of the filter with guaiac tincture produces a blue color. The property of pus to color guaiac tincture blue depends in all probability on the influence of nucleo-proteids—this is seen even in extreme dilution. Nucleo-proteids extracted from various tissues do not give this reaction—only the nucleo-proteids derived from the leucocyte group (bone-marrow cells). Tissue abounding in lymphocytes, *e.g.*, adenoid, does not give this reaction.

Absorption and Fat-Splitting in the Stomach.—Franz Volhard concludes from his work on this subject that an extensive splitting of finely emulsified egg and milk fat takes place in the stomach. He believes Mering's method, in which the Soxhlet apparatus is used and the fatty fluid is spread over clay and dried with dry sodium sulphate, is the simplest and most convenient.

A Preliminary Communication on a New Staining Method for the Determination of the Finer Structure of Bacteria.—K. Nakarishi describes a new method of staining with methylene blue which has met with successful results. He has tried many aniline colors, and considers methylene blue best suited to this work.

Two Cases of Beri-Beri (Panneuritis Endemica Balz) on Board a German Steamer.—P. Schmidt, after submitting these reports, states that much microscopical work has been done to elucidate the etiology of this disease. But the work of both European and Japanese physicians has yielded no valuable results.

Some Remarks on the Basophilic Granules in the Red Blood Discs.—Martin Cohn thinks it most probable these granules are the result of protoplasmic degenerations which depend to a certain extent on the chemical alteration of the blood serum, since they are always present in anæmia.

Ischiadic Scoliosis.—Krecke is of the opinion that the bowing is not caused by functional incapacity nor by paralysis or contracture of the sacro-lumbalis, but comes from the patient's tendency to shift all the burden of effort on to the side that is not painful.

The Application of Gelatin for Checking Cholæmic Hemorrhages after Operations on the Biliary System, besides Remarks on Poppert's Waterproof Drainage of the Gall Bladder.—By Hans Kehr. A continued article.

Reports of Cases of Skull and Brain Injuries.—Carl Fröhlich reports two cases of this nature, the first of which ended in recovery, while the latter developed traumatic encephalitis after a year and resulted fatally.

Deutsche med. Wochenschrift, February 8, 1900.

The Diagnosis of Incipient Tuberculosis from the Sputum.—L. Brieger and F. Neufeld hold that (1) the sputum should be examined not only for tubercle bacilli but also for other bacteria, especially for those of the so-called mixed infections; (2) the examination should be repeated at intervals if no tubercle bacilli are found at first; (3) in any case the clinical symptoms must be carefully studied, for it is only by a comparison of the clinical and bacteriological findings that one can arrive at any satisfactory diagnostic and prognostic conclusions; (4) whenever repeated examinations leave the diagnosis uncertain, recourse should be had to the tuberculin test, which is positive and at the same time free from danger.

Turners' Palsy.—E. Lehrwald describes, under the title "Klimmzuglähmung," a form of paralysis induced by the strain of raising the body by the arms, the hands grasping a horizontal bar. In a reported case the trouble appeared quite suddenly and involved the deltoid chiefly, but also the biceps and in less degree the brachialis internus and supinator longus. The paresis was accompanied by atrophy of the affected muscles. In another case the paralysis was much more extensive. The author believes this affection is not very uncommon among weak and unskilful gymnasts, and says such persons should be warned against persisting in the offending exercises when they cause pain or excessive fatigue in the arms.

Treatment of Ulcerative Stricture of the Rectum.—Julius Wolff reports a case of stricture of the rectum following ulcer in which, after unsuccessful attempts to cure by less heroic measures, an extensive resection of the wall of the rectum was made. Healing did not take place, the stitches gave way, and the final result was an enormous opening at the anus, with consequent prolapse of the rectum. A resort was now had, many months after the primary operation, to a plastic operation, whereby the posterior wall of the rectum was re-formed with a skin flap, and the divided ends of the sphincter were freshened and reunited. The operation was a complete success.

Spondylitis Rhizomelica.—M. L. H. S. Menko reports a case of this affection, described first by Bechterew as chronic ankylosing inflammation of the spine and large joints, and later called by Marie "spondylose rhizomélique."

French Journals.

Experimental Study upon the Parasitism of Tumors.—W. Podwyssotski, basing his experiments upon the classical study by Woronin of the excrescences found upon the roots of plants—especially the cabbage—and taking the plasmodiophora brassicæ as the type of productive agent in parasitic tumors in the vegetable kingdom, studies the effect of such parasites upon animal tissues. He inoculated rabbits and guinea-pigs with small masses of the root of diseased cabbage containing the parasites in the stage of sporulation. Round or oval tumors formed, showing masses of cells much like those in leprous granuloma or large-celled sarcoma. The infiltration began in the perivascular lymphatic spaces. The cells of the tumor were filled with round corpuscles, of red blood corpuscle size, surrounded by a very thin membrane and containing very fine fat granules. The parasite produced an irritation of the cell nucleus, which enlarged, and to the presence of the parasite were attributed the hypertrophy and cellular proliferation. A number of illustrations show the microscopic appearances of what the experimenter believes are parasitic tumors or myxomycetic granulomas of mesodermic origin, produced in animals by the plasmodiaphora. In reference to the great question of cancer, he thinks his results show that a cellular inclusion of undoubted parasitic nature may be almost invisible in the protoplasm of the tumor cell, and that scepticism should not go to too great lengths because of the difficulty of discovering parasites.—*La Presse Médicale*, February 14, 1900.

Pulmonary Embolus in Phlebitis.—M. de Treigny considers the various causes for this sudden accident in the course of phlebitis when nothing indicates the imminence of the danger. Instances are cited. Curative treatment is purely symptomatic. He mentions the success obtained by Oeder by means of injections of camphorated oil every five minutes until 2.4 gm. were administered in an hour. Isch-Nall resected the veins as a prophylactic measure after a series of slight embolic attacks. Extirpation of suppurating phlebitis of the cord is also mentioned. Immobilization is a necessity, and before permitting a patient to get up or to receive massage after pregnancy, pelvic tumor, abdominal operations, convalescence from typhoid and other severe fevers, as well as fractures, we should assure ourselves by methodical exploration of the venous system that there is no sign of deep-seated coagulation.—*Journal des Praticiens*, February 10, 1900.

Treatment of Vaginismus.—Dr. Verchère says the first advice to give a woman suffering from vaginismus is to suppress all genital excitation, since absolute and prolonged rest of the organ may of itself alone bring about a cure. Iodoform is recommended as a dressing, being anæsthetic as well as antiseptic, and is usually efficacious. Various methods of treatment, from cold sitz baths to divulsion and cutting operations, are passed in review. The Sims method is in a general way regarded as too radical. Two successes are reported from subcutaneous section of the anal sphincter. Medical treatment is of great importance. Much attention must be paid to subjects predisposed to hereditary insanity. Antispasmodic and tonic treatment is usually indicated, while hydrotherapy and arsenical treatment are not to be forgotten.—*La Médecine Moderne*, February 14, 1900.

Renal Function in Chronic Nephritis.—L. Bernard finds that renal permeability is not uniform in all nephritis; there is a nephritis with permeable and a nephritis with impermeable kidney. There is no necessary relation between the existence of uræmic phenomena and those of renal impermeability. The term parenchymatous and interstitial as applied to nephritis are considered unfortunate. The evolution of each is different. The evolution in two periods of the nephritis termed parenchymatous is not a transformation into interstitial nephritis. We should say that at a given moment it becomes complicated with sclerous lesions which carry with them renal impermeability and its attending symptoms.—*La Presse Médicale*, February 17, 1900.

Reflections upon Muco-Membranous Colitis and Appendicitis Produced in the Course of this Disease.—Louis Beurnier says that authors are agreed that subjects of muco-membranous colitis are neuropaths. He has found this to be the case in all his patients. In a case reported, the symptoms led to an operation for appendicitis. The appendix was found healthy in appearance and under the microscope. The whole trouble was due to absolute fusion of the epiploön with the large intestine, the cementing process extending to the upper limits of the ascending colon. —*Journal des Praticiens*, February 10, 1900.

Il Policlinico, February 1, 1900.

Albuminuria in Diabetes and Renal Diabetes.—In an article concluded from the preceding number, Ferruccio Schupfer states, among the many conclusions drawn from his cases and experiments, that the albuminuria in diabetes may be due to (1) over-functioning of the kidneys; (2) diabetic coma; (3) cystitis and pyelitis; (4) the excessive ingestion of eggs; (5) nervous influences; (6) the passage of microbe toxins through the kidneys; (7) stasis; (8) renal hyperæmia; (9) parenchymatous nephritis; (10) shrinkage of the kidney. Cases published under the name of renal diabetes were merely ordinary cases of diabetes, in which the glycosuria disappeared or was diminished when a nephritis developed after the diabetes.

The Disappearance of the Red Corpuscles Stainable by Methylene Blue in the Blood in Grave Anæmia.—Vittorio Belli says that the presence of these corpuscles is not constant, but varies at different times of the day. The gravity of anæmia is shown rather by the frequency of the appearance of these cells than by their number or the depth of their coloring. Their absence shows improvement and cure of anæmia only when confirmed by repeated examinations during the course of the day.

Influence of Diphtheritic and Typhoid Toxins on Nutritive Exchange.—Domenico Pace concludes his article from a previous number, already abstracted in these columns, with tables illustrating the conclusions reached.

Chorea.—Angelo Ruffini calls attention to the fact that in 1892 he claimed that chronic chorea was due to slow and progressive atrophy of the ganglia of the motor zone of the cerebral cortex.

Journal of Tropical Medicine, February, 1900.

Notes from Lagos, West Africa.—Henry Strachan notes that the greatest prevalence of malarial fever in the tropics occurs shortly after the cessation of the rains, and that there are few cases during the rains unless these have been interrupted by short periods of dry, hot days. In other words, the malarial curve parallels that of the rise of subsoil water, and follows by some days that of the rainfall. When the ground is saturated, surface puddles which afford breeding-places for Anopheles are more readily formed and last longer. The same writer records his belief that blackwater fever is possibly a disease distinct from malaria. He says, in support of this opinion, that hæmoglobinuria occurs all through the year independently of the varying prevalence of malaria, and that the salicylates are more curative than quinine.

An Undescribed Form of Plague Pneumonia.—William C. Hossack reports five cases of an indefinite form of plague, which is especially important because of the danger of its escaping recognition. It is a pulmonary form, beginning insidiously, the general symptoms at the end of five or ten days being perhaps no more severe than they would be in a case of simple bronchitis, while the local lung symptoms are very vague. As a rule, there are no enlarged glands. Death occurs suddenly and unexpectedly from the fifth to the tenth day. The most striking feature is the pulse, which is weak and rapid, out of all proportion to the apparent local or general condition.

Typhoid or Malarial Fever.—W. E. de Korte discusses the diagnosis between adynamic remittent malarial fever and typhoid fever as observed in South Africa. There is a fever there which the public calls "slepende" or dragging fever, and for which no medical advice is sought; but when it suddenly becomes acute, with rise of temperature, the physician steps in and calls it typhoid. In such cases the writer has found the plasmodium malariæ. He does not deny the existence of typhoid fever in South Africa, but contends that many fevers so called are really malarial.

Plague in Siberia and Mongolia and the Tarbagan.—Frank G. Clemow reviews accounts in Russian journals of an endemic disease in several places in Siberia and eastern Mongolia, which has many points of superficial resemblance to the bubonic plague, although proof of identity of the two affections is wanting. The disease in Siberia seems to be connected with an endemic affection of the tarbagan (Arctomys bobac), a rodent of the nature of a marmot.

A Contribution to the Diagnosis and Treatment of Æstivo-Autumnal Malaria.—J. Preston Maxwell says this form of fever is much more refractory to the action of quinine than benign malaria, yet the prompt use of quinine by subcutaneous injection at the beginning of an æstivo-autumnal attack may avert the threatening paroxysm. He reports a case in support of this conclusion.

Clinical Report of Four Cases of Suspected Yaws or Frambœsia.—W. S. Griffith reports these cases occurring in a Kaffir woman and three of her children. The diagnosis rested between syphilis and yaws, and the writer inclined to the latter.

Monatsschrift für Geburts. und Gynäk., February, 1900.

Puerperal Tetanus.—Hans Kentmann says that although puerperal tetanus is the most frightful complication of the puerperium, it is also the most infrequent. This affection is rare in the northern zones, but comparatively frequent in the south. In a series of forty-three cases, the first symptoms of the disease appeared on the average nine days after confinement, the longest period being nineteen days and the shortest four. As to treatment, the severe cases do not seem to be influenced by antitoxin. It is important to eliminate the original focus of the disease, but irrigation, curetting, and even total extirpation of the uterus have not yielded the desired results. The prognosis is unfavorable. Kentmann relates the history of a case, and then speaks of the colossal power of resistance of the tetanus spore.

The Application of Hot Steam in Gynæcology.—R. v. Steinbüchel speaks of some of the affections in which the local employment of hot air and steam was followed by good results—dysmenorrhœa, endometritis with hemorrhages or with copious discharge, subacute or chronic uterine gonorrhœa, subinvolution of the uterus, myoma if the uterine cavity is not irregular in contour, carcinoma with hemorrhage and fetid secretion, hemorrhages after abortions, putrid endometritis. In order to obtain obliteration of the uterine cavity, the application of a temperature of 110° to 115° F. for a period of two minutes is necessary. When obliteration is not the aim, the steam is applied for only seven to ten seconds. Although the results from the short applications are less certain, still in this method stenoses and unintentional obliteration do not follow.

Can the Place of the Appearance of the Contraction Phenomenon be Determined in a Purely Anatomical Way without Objection?—Otto v. Herff concludes from his work on the living woman that, in order to designate any one place as the point in the uterine wall where the contraction phenomenon originates, this particular point must be proved never to shift. This result has not yet been attained.

Fibrinous Placental Polypi.—W. Langhans believes that dependent on every conception there occur certain polyp-like masses in the uterus, consisting of blood clot; these masses are pedicled, and situated generally in the fundus, hanging down either into the expanded uterine cavity or the expanded cervical cavity. They are capable of no further organization, and they have no relation to new growths.

Two Cases of Fibrosarcoma in the Broad Ligament.—Axel R. Limnel, in speaking of these two cases which he has treated, believes that the most probable origin of the fibrosarcoma was in the broad ligament, for it was not in the uterus, ovary, parovarium, or Gärtner's canal. The diagnosis is difficult and the condition is often mistaken for ovarian tumor.

Dystocia Caused by the Contraction Ring.—J. Veit-Leiden, in discussing this subject, concludes that there is no proof of the isolated condition of contraction of Bandl's ring without simultaneous contraction of the whole muscle surface of the uterine cavity.

Revue de Chirurgie, February 10, 1900.

Radical Cure of Large Umbilical Hernia.—M. K. Sapiejko describes the case of a woman, four months pregnant, with an enormous umbilical hernia. After making an incision, which extended from the xiphoid appendage to the symphysis pubis, he separated the skin from the aponeurosis the whole length of the incision, at a breadth of six inches at the umbilicus, narrowing above and below. He then fixed the left border of the aponeurosis to the right peritoneal surface by a continuous suture, and the right border to the left side. By this means the anterior part of the abdomen, formed of peritoneum, muscles, and aponeurosis, was made up of a double layer of these tissues. The skin was then sutured, after removal of two elliptical flaps.

The Treatment of Cancroids without Extirpation.—Charles J. Rossauder reports cases in which the injection of a one- to one-half-per-cent. solution of potassium hydrate into cancerous tumors has given good results. He believes that these injections, although not sufficiently strong to have a cauterizing effect, do provoke an irritation of the connective tissue around the tumor and in the capillaries, leading to coagulation of the blood and obstruction of the blood-vessels. Necrosis of the tumor is not produced, but its vitality is diminished and new growth inhibited.

The Treatment of Fractures of the Clavicle.—L. Gratschoff, after reduction of the fracture, uses an immobilizing apparatus, the essential features of which are a shoulder cap, an iron rod placed so that one end corresponds to the apex of the acromion process, and the other to a point one and three-fifths inches below the nipple of the normal side, with a four-part bandage going over the unaffected shoulder, around the hip of each side, and across the front. All start from the inferior end of the iron rod. Supplementary bandages support elbow and forearm. Two cuts illustrate the description.

Iliac Colostomy by Double Ligature.—Michel Gongolphe describes sixteen cases in which his operation has been perfectly successful and satisfactory. After making an abdominal incision, he draws out a loop of the ileo-colon and strangles it with a double-chain ligature. He fixes it to the wall, cutting it off from the peritoneal cavity, and forty-eight hours later removes it by the thermo-cautery without anæsthesia. The inferior end is left open in the iliac wound.

Metatarsalgia.—Niccolas Giannettasio reports a case, giving the radiographic and histological findings. The cartilage was found to be much diminished in thickness, and the cartilage cells were dispersed in elongated capsules.

Total Splenectomy.—Andrès F. Llobet describes an operation performed in a case of displacement and hypertrophy of the spleen, with primary cancer of the pedicle.

Tumors of the Biliary Ducts.—By F. Terrier and M. Auvray. A continued article.

Jour. des Maladies Cutanées et Syphilitiques, Jan., 1900.

Blennorrhagic Infection and Marriage.—Ignacio Callari concludes an essay with the suggestions that popular instruction should be given upon the perils of the disease in order that they may be lessened. Young people should be warned against a poisoned union and compromised posterity. They should be deterred from marriage while diseased by appealing to their honesty, reason, and interest, and they should be taught especially the necessity of thorough cure.

Transmission of Ecthyma by Direct Contagion from Animal to Man.—Le Calvé and H. Malherbe present an observation with bacteriological control experiments, in which a lady contracted the disease from a pet dog. Inoculation of another animal with the germ resulted in typical ecthymatous lesions and a general infection ending in death.

Ann. des Mal. des Organes Génito-Urinaires, Feb., 1900.

Bacteruria.—A. Gassmann gives notes of a case of bacteruria with remarks upon the diagnosis of prostatitis. The number of published cases of bacteruria according to Krogius' definition is still restricted. The present case originated in seminal vesiculitis. Urotropin and salol in ordinary doses are not capable to preventing development of cocci. The best results are obtained by instillations of silver nitrate.

Hypertrophy and Epithelial Neoplasms of the Prostate.—J. Abarrau and N. Hallé give fifteen observations in a continued article.

Ann. de Dermatologie et de Syphiligraphie, Jan., 1900.

Impetigo.—R. Sabourand presents his first memoir upon the clinical and bacteriological study of impetigo. He distinctly separates, in this the clinical portion, impetigo contagiosa of Tilbury Fox, from the superficial pustular impetigo of Bockhart developing about a hair.

The Question of Eczemas.—Brocq gives sixty-one pages of a continued article. Circinate seborrhœal eczema is set apart as an affection of probable parasitic nature. The opinions of various observers as to the varieties of so-called seborrhœal eczema are presented.

Norsk Magazin for Lægevidenskaben, February, 1900.

A House Epidemic of Diphtheria.—C. M. F. Sinding-Larsen describes an epidemic of diphtheria occurring in the Seashore Hospital for Scrofulous Children at Fredriksværn. The epidemic began with two cases at the end of December, 1898, and, in spite of repeated examination of all the children, and isolation not only of those presenting actual symptoms, but also of those in whom bacilli were found in the throat and nose (latent diphtheria), and disinfection of the wards, the end of the visitation was not until October 12th of the same year. During the epidemic there were seventeen clinical cases and twenty-seven latent cases.

Gelatin in the Treatment of Aneurism of the Abdominal Aorta.—J. Buchholz reports a case of abdominal aortic aneurism in a woman aged thirty-five years. The treatment consisted in rest, the application of an ice-bag day and night, and the internal administration of six ounces daily of a five-per-cent. solution of gelatin. At the end of three months of this treatment the patient was cured.

The Parasite of Cancer.—B. Vedeler describes the results of a careful parasitological examination of an adeno-carcinoma of the ovary, in which he found a micro-organism (pictured in the colored plates accompanying the article), which he believed to be pathogenic, though the proof of cultivation was wanting.

Correspondence.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From Our Special Correspondent.)

During the 14th and 15th of February, as every one knows, Lord Roberts made a curving advance upon Kimberley, which had the result of relieving the town and of forcing General Cronje to retreat from his entrenched positions toward Bloemfontein. The sanitary condition of Kimberley was found fairly good, although the mortality among the children had been terrible. In forty-eight hours railway connection was established between Cape Town and Kimberley, and trains full of supplies were running northward, while hospital trains were carrying the sick down to the base hospitals. The inhabitants of Kimberley were beginning to suffer from scarcity of food, especially of vegetables and milk, and the supply trains were the most efficient medical aid that they could have received. The New South Wales medical corps, the medical staff corps organized and equipped by Australia, distinguished itself in the relief operations. The ambulances, drawn by excellent Australian horses, kept pace with General French's flying cavalry column and picked up the wounded. The corps received many compliments for its excellent work.

General Hospital No. 4.—The first three general hospitals are, as I have said, situated near Cape Town, but General Hospital No. 4 is in Natal on the Mooi River, a tributary stream running northward into the Tugela River. It is constructed to accommodate five hundred sick and wounded, which should amply suffice for the wants of General Buller's force, for it must be remembered that this force has behind it a big hospital of one thousand beds at Pietermaritzburg as well as a stationary hospital at Estcourt. To this hospital Mr. Frederick Treves, certainly the operating surgeon of the widest repute in England at the present moment, has been attached, and did excellent operative work after the unfortunate attempts to relieve Ladysmith. But I learn by telegram that on February 20th he was prostrated with dysentery and had to go down to the coast to recover. There has been a good deal of dysentery and enteric fever among both officers and men of Buller's force. The routine treatment for dysentery at the Pietermaritzburg hospital is purgative doses of sulphate of magnesia, and, though the treatment is painful, Mr. Treves considers it to be on the whole successful, more successful than the exactly opposite treatment by opium. General Hospital No. 4 was made at its start the subject of severe criticism by the *Times of Natal*, a paper of some standing in the colony. The *Times of Natal* said that the administrative authorities had failed, that stimulants and medicine were forthcoming only after long delay, that the nursing was inadequate, that the food supply was deficient, and that while tons of stores lay at Durban undistributed, the hospital depended upon charity for such necessaries as pajamas and pillows. The accusations of the *Times of Natal* were founded upon completely incorrect information, as was at once pointed out to the editor, but they have provoked a feeling in Durban and Pietermaritzburg that, while so much has been done for the base hospitals at Cape Town, not enough has been done for similar institutions in Natal. The Mooi hospital is, as a matter of fact, well found and excellently managed; but it is quite possible that there was at first some disorder among the administrators in Natal, for it must be remembered that all the preparations were originally made in England under the idea that the chief fighting would be first in Cape Town, but that when the army arrived at Cape Town most of it had to go on at once to Durban to attempt the relief of Ladysmith. The change of programme may at first have led to some confusion, but for many weeks matters have been running quite smoothly. One thing, and as yet one thing only, can be fairly alleged against the medical administration in this war—*i.e.*, not enough female nurses have been provided, too much reliance having been placed upon the administrations of orderlies, better fitted to act as porters than as assistants in the dressing of wounds.

Two More Voluntary Hospitals are proceeding to the Cape, the Princess Christian Hospital and the Welsh Hospital. That there should be a Welsh hospital set on foot, as soon as a Scotch hospital and an Irish hospital were announced as starting for the seat of war, was a foregone conclusion; for Wales is very tenacious of its right to be considered a separate nation. A provisional committee has been formed in London for raising the money to equip a Welsh hospital, the following well-known medical men being responsible for the movement: Sir John Williams, physician accoucheur to University College Hospital; Dr. Frederick Roberts, physician to the same hospital; Mr. Edmund Owen, surgeon to St. Mary's Hospital; Mr. Thomas Jones, professor of surgery in Manchester; and Prof. Alfred Hughes, professor of anatomy in King's College, London. The Princess Christian Hospital, which will sail from Southampton at the end of February, has been presented to the government by Mr. Alfred Mosely, a native of Bristol. It is a completely equipped hospital of one hundred beds. Mr. Paul Bush, surgeon to the Bristol Royal Infirmary and lecturer on operative surgery at University College, Bristol, goes out as chief surgeon, and Major Mathias, R.A.M.C., is the government medical officer. The hospital has been called "Princess Christian" in recognition of the work done by Her Royal Highness Princess Christian of Schleswig-Holstein in the nursing-world, and possibly in compliment to her eldest son, Prince Christian Victor, who is at the front, and distinguishing himself as a major in the Sixtieth Rifles.

OUR LONDON LETTER.

(From our Special Correspondent.)

STORMS — INFLUENZA — MORTALITY RETURNS — MOSQUITOS — AMYLOID DISEASE — CHOLERA TOXINS — CHOREA — HÆMOPNEUMOTHORAX — DUODENAL ULCER — PRINCE OF WALES' HOSPITAL FUND — SIR M. FOSTER ELECTED M.P. — THE LATE DR. HYDE — THE WAR — THE ARMY SURGEONS — MORTALITY RETURNS — WEATHER — THE MIDWIVES BILL AND THE GYNÆCOLOGICAL SOCIETY — A PLEBISCITE OF THE PROFESSION — MASTOID DISEASE — CLINICAL EXHIBITION OF THE MEDICAL SOCIETY.

London, February 16, 1900.

Frost, snow, blizzard! a long chapter of accidents with corresponding pressure in the receiving-wards of the various hospitals; these have been the distractions of the last few days, and so immediately affecting us as to hold attention above everything, unless it be the more serious subject of the war. To-day, however, a change of wind and clearer sky make us more cheerful with the promise of less discomfort.

The effect on the mortality returns will not be perceived for a week or more. The London death rate for last week was 20.4. In the thirty-three principal towns of England and Wales it was 22.8. There was a sudden rise in the north of England. It marked 32.3 in Blackburn, 31.8 in Liverpool, 35.1 in Preston, 34.2 in Salford, 28.4 in Leeds, and 28 in Manchester.

Influenza is responsible for a considerable share in these high rates, as the epidemic has passed northward, where so many workmen are kept at home that the collieries and factories are very greatly inconvenienced, some of them being brought nearly to a standstill.

In London the epidemic continues to decrease. The deaths from it last week fell to sixty-three. In the first two weeks of the year the numbers were three hundred and sixteen and three hundred and forty-nine. This was the highest point reached. A substantial drop followed, the succeeding weeks showing two hundred and eight, one hundred and fifty-two, and one hundred and nine. Now with this week's fall to sixty-three we may consider the epidemic practically over. Ireland has also suffered from influenza, which is one of the causes of the abnormally high mortality in Dublin, Cork, and other cities. The rate in both these passed fifty in December, and in Cork was fifty-eight in January, but in both there has since been a fall. Typhoid and measles have contributed to their mortality.

Mr. Pearce Gould, senior surgical vice-president of the Pathological Society, has been requested by the council to act as president during Mr. Cheyne's absence in South Africa. Accordingly he presided at the last meeting, when he paid an appropriate tribute to Dr. Charlewood Turner, whose death I mentioned in my last. Dr. Nuttall then demonstrated a number of microscopic lantern-projections illustrating recent discoveries as to the part played by insects in spreading infective diseases, particularly that of mosquitos.

An account of experiments made by Dr. A. Green to test Krakow's statements on the production of amyloid disease was then given by Mr. S. Pigg. The experiments were made with cultures of staphylococcus pyogenes aureus injected subcutaneously in rabbits and fowls. The results were mostly negative, but in the case of one hen Dr. Green obtained the mahogany stain with iodine. No definite amylaceous change could be found in the twenty rabbits experimented on.

Dr. W. Myers reported his researches on the neutralization of cobra venom by Calmette's antitoxin. The venom seemed to contain two toxins, one hæmolytic, the other a nerve toxin. The former is destroyed before the latter when venom is gradually heated. In a concentrated form the venom retains its strength, but a dilution of one per cent. loses strength by keeping.

Dr. Bertram Abrahams then showed lantern slides and microscopic specimens illustrating the changes in the parietal cortex of a woman aged twenty-eight years who died on the thirty-seventh day of an attack of chorea gravidarum. These changes were similar, though less in degree, to those described by Dr. F. W. Mott in cases of status epilepticus, and as in them it was thought that the alterations in the cells depended on modifications in the chemical condition of their lymph environment. Moreover, their nature and extent were obviously compatible with complete recovery.

Hæmopneumothorax presents puzzling problems to the physician. There were two cases related at the Clinical Society and others mentioned by subsequent speakers. Dr. Rolleston related one in a man aged twenty-one years who after two days of diarrhœa was seized with pain in the right hypochondrium radiating to the umbilicus and right shoulder. He seemed moribund on admission, but rallied, and next day had signs of right pneumothorax with displacement of the heart. Paracentesis brought out blood and air at considerable pressure. Death occurred eight days after. The right pleura contained sixty ounces of blood but no air. No explanation was found. There were no signs of tubercle, pleurisy, hæmophilia, scurvy, cirrhosis of the liver, aneurism, or traumatism.

The other case was related by Dr. Newton Pitt. It was of a man aged eighteen years, who had sore throat and diarrhœa for three days and was then seized with pain and collapse. Six or seven hours after there was evidence of acute pneumothorax, with dulness over the right base and displacement of the heart, the impulse being two inches to the left of the nipple line. To relieve the pressure a Southey's tube was inserted in the sixth interspace in the axilla, and blood flowed, to the surprise of the doctors. Another puncture had the same effect, and as no relief followed it was concluded that hemorrhage was continuing. He died that evening. At the post-mortem eight pints of fluid blood besides clots filling the hand three times were found. The heart, aorta, and pleura were normal. There was no tubercle or necrotic change in the lung, but there was one emphysematous bulla about half an inch in size, torn open at the apex and attached to this a ruptured adhesion, the size of a knitting-needle, from which perhaps the blood may have come, but no aneurismal pouch or patent vessel was discovered. This case seems rare, if not unique.

Dr. Hingston Fox referred to the case of a man aged forty-four years who was taken with pleurisy and was tapped on the tenth day, when fourteen ounces of dark blood came away. Three days later signs of pneumothorax came on and the operation was repeated, forty-five ounces of blood coming with much air. The patient recovered.

Sir D. Duckworth thought that in these cases rupture of the lung with pneumothorax was followed by the hemorrhage, and behind all was tuberculosis.

Dr. S. West mentioned a case of pyopneumothorax in which pus was evacuated, and this was followed by hæmoptysis. At the post-mortem an old tuberculous cavity into which an aneurism had burst was found. As the cavity communicated with the pleura blood escaped both ways.

Sir D. Powell (president) said the precedence of hæmo- and pneumothorax wanted clearing up. In an experiment he could not pump more than six or seven pints of fluid into the pleura. He thought it curious for the blood to remain fluid in the presence of air.

Dr. Pott in replying mentioned that in looking up the literature he found cases in which eleven and twelve pints were said to have been removed.

Drs. Perkins and Wallace related a case of perforating duodenal ulcer on which they had operated with success, convalescence being uninterrupted. The whole abdomen was irrigated, the intestines being turned out for the purpose.

Mr. Barker took exception to this, as he did with regard to gastric ulcer in a discussion I lately noticed. He thinks the less the abdomen is meddled with the better, as the peritoneum can dispose of much septic matter.

Mr. Gould doubted the septic state of the contents of the stomach, though they are very irritating.

Mr. C. Symonds rather agreed with Mr. Barker as to the risk of evisceration, and recommended a medium plan, viz., flushing and then mopping with gauze.

Dr. Poynton thought duodenal ulcer more frequent than is generally supposed. In two years' necropsies at St. Mary's Hospital he had seen eight such lesions and met other cases in the wards. All were chronic with thickened, raised edges, and had formed adhesions. Prolonged dyspepsia with severe pain was present in some of the cases for five to ten years. Extreme severity of the pain was suspicious.

Sir Michael Foster has been duly elected member of Parliament for the University of London. He made a short speech to those present, remarking that this is the first time the graduates had elected one of themselves. He took it that his fellow-graduates did not send him to Parliament simply to add one more unit to either political party, but that he should place at the disposal of the House his special experience in science and learning. He would take his seat at first among supporters of the government. The old cry of civil and religious liberty made him prick up his ears. He was born in the same town as Oliver Cromwell, and his forefathers harbored John Bunyan when he preached outlaw sermons in the wilds of Hertfordshire.

The Prince of Wales presided at the annual meeting of the council of his hospital fund. The receipts for 1899 exceeded £48,500, showing an increase of about £9,000 on the amount for 1898.

I regret to record the death of Dr. Samuel Hyde, of Buxton, at the early age of fifty years. A native of the town, he settled there soon after qualifying. He was chairman of council of the Balneological and Climatological Association, and editor of its journal. He wrote many contributions on the effect of waters, especially those of Buxton. His "Buxton, its Baths and Climate," reached a fourth edition in 1898. His treatise on "Rheumatoid Arthritis" appeared in 1896. Many other articles from his pen on allied subjects have been published. Last summer his active life was interrupted by obstruction of the bowels, for which colotomy had to be done. He rallied well, and was able to absent himself from home for some time so as to gain rest, but complete recovery was not to be, and he sank and died on the 8th instant.

February 23, 1900.

The war makes such demands on our attention that other subjects seem to be of minor importance. Nevertheless we pursue our usual routine of work, and engage with some interest in professional conversations and discussions. Newspapers, of course, are full of the war, and the medical journals are occupying themselves with it more than ever before. The civil surgeons at the front send letters giving their impressions of the hospitals and cases. We read them with some interest, but an increasing conviction that they are of no use out there except to assure the public of the excellence of the military surgeons and of the arrangements of the army medical department. The fact that so far this branch has made no blunders is making a strong impression on the public. At length the Duke of Cambridge has found words of praise for the Royal Army Medical Corps and its work. At a critical inspection of the Langman Hospital on Wednesday His Royal Highness warmly congratulated the generous donor and all concerned. Then he expressed his gratification that every class in the empire had shown splendid spirit and done its best. Then he added "No class has done more in the work of the campaign than the medical men." This from the late commander-in-chief is praise indeed. In office he never did justice to the medical officers, and always opposed any redress of their grievances. The stress of war seems to have converted him. Will his successor now make the *amende honorable* and indorse the praise of His Royal Highness?

Rapid variations in the weather, disastrous floods succeeding the snow and storms, with the usual consequences to the public health—these are the characteristics of the week, though one day seemed to bring promise of spring.

The mortality returns are not yet satisfactory, though the epidemic of influenza is nearly over. In the thirty-three great towns the average death rate was 25.8. This is an advance, but it must be remembered that it shows the deaths registered, not those taking place in the week. The rates of the three preceding weeks were 22.6, 21.2, and 22.7. In London the rate was 22.9; Birmingham, 33.4; Manchester, 37.2. There is a very remarkable return for Preston, 54.8. If some error or misprint has not crept in, this calls for investigation.

Midwives, no doubt, will always be with us in some form or other, but why, oh why, must a midwives bill be forever troubling us? And why should the questions involved stir up more passion than reason? Here we are threatened with a possible second reading next week of a most obnoxious measure promoted by a set of interested persons who play on the feelings of the public. Their proceedings and object may be judged by the fact that they have not hesitated to issue an advertisement in the daily press urging that "all married people should agitate to secure the passage of the bill," telling them it "will practically abolish the system of man-midwifery by creating a class of properly trained, qualified, and registered midwives who will be employed with perfect confidence in all cases." And the very people who resort to such methods of agitation declare privately that their scheme cannot injure the profession, and they pretend, too, that their clients will attend only normal cases. Those who look forward as well as backward tell us that once certified and registered these gossips can no more be restrained from practice on all the women and children they can reach, than the old apothecaries could be hindered from becoming full practitioners as soon as they were properly educated and licensed. And a number of consulting obstetricians who are assisting the agitation are declaring that they do so out of pure benevolence and pity for women laboring with child. Their opponents sneer at this, and say they only want to be called in to help the midwives. If such be their motive they can hardly expect ever to be consulted by the men whose bread they would take away to bestow it on the women who would practically be their partners. It is certainly a fact that there is qualified aid at the disposal of all parturient women in England, and that being so the only women allowed to compete should be fully qualified too—and not mere midwives or nurses. Women can enter the profession; an increasing number are doing so. Their interest is to resist the encroachment of the midwives and support the present law of the land that every registered practitioner must be qualified in our three branches—medicine, surgery, and midwifery.

Amid the din of controversy that has been provoked on the question the voice of Dr. W. J. Smyly, of Dublin, has been heard and deserves an acknowledgment of his tolerant attitude. Dr. Smyly has been elected president of the British Gynæcological Society, and came over to deliver his inaugural address on the 8th inst. He is a past master of the Rotunda, which some think the first obstetric school in the world, and his experience extends to midwives, for they are taught at the Rotunda, and Dr. Smyly considers with benefit to the public. He, however, objects to the proposed bill because it does not apply to Ireland. This is certainly a new grievance from the Emerald Isle, and withal a little inconsistent with the proposition that the Rotunda has worked so well for one hundred years. The opposition of the general practitioners in England is more significant, as they constitute the *corpus vile* on which the experiment is to be tried. If successful, happy Ireland would soon claim her share of the benefit. Dr. Smyly touched on the threat once made to charge the Rotunda officers before the Medical Council. That was foolish, as the Rotunda has the authority of a royal charter. Very different is the position of the Obstetrical Society of London, which has not a vestige of authority for granting its diplomas, in which it does a profitable business. Even the general medical council—the slowest of all slow bodies to move—condemned the Obstetrical Society's trade and threatened to prosecute its managers, but to the disgust of all reformers it soon after climbed down, and there is still a brisk demand for the sham diplomas. With the holders of these competing for practice, no wonder the English general practitioners object to an inferior grade of partially qualified persons being shoved upon them.

Dr. Smyly told the society that in Ireland no distinction is made between monthly nurses and midwives, and he thought it unfortunate that in England the same plan is not followed. A midwife who met with a complication in Ireland at once sent for a doctor and remained as nurse with the patient.

At the conclusion of the address, Dr. Macnaughton Jones (the retiring president) proposed the vote of thanks. In doing so he said the society took a moderate view and was practically in accord with the medical council. He remarked too that every registered practitioner was a midwife, and he objected to anything which would impair the traditions and prestige of the obstetric art.

The vote was seconded by the venerable Dr. Routh, who contrasted the present teaching with that when he was young. He said we must have midwives, but they should be kept in their proper places.

In view of the possibility of the bill coming on in the House, *The Lancet* has issued a post-card plebiscite asking for a plain yes or no to questions put in order to show whether the profession is for or against the bill, and, further, for or against any legislation on the matter.

The adjourned discussion on mastoid disease at the Medico-Chirurgical Society took place on the 13th inst., but it cannot be said to have added to our knowledge of the subject. It gave indeed an opportunity for some surgeons to express an opinion on the operations which have been performed, and for others to repeat or supplement their former statements. The subject is one for specialists, and Mr. Barker said naïvely that "this department of surgery was in one sense a legitimate specialty," a grudging admission quite characteristic of general surgeons. These gentlemen praise Mr. Ballance because he is a general surgeon of a very high position, but as he has been a diligent worker in "this department of surgery" for some fifteen or sixteen years, and is aural surgeon at St. Thomas' Hospital, the aurists naturally look upon him as one of themselves. His position, training, and experience combine to make him an ideal aural surgeon, and otology is unquestionably a surgical specialty. His treatment described at the former meeting is, as I told you, a twofold operation, the first for the cure of chronic purulent otorrhœa, the second for healing up the wound by epithelial grafting of the raw bone cavity. The disadvantage, or, as one speaker called it, the defect, of the proceeding is the double operation and the possibility of having to resort to a third reopening for the removal of the gold-leaf which Mr. Ballance employs. He, however, has not had to do this. Indeed, he said the patient was quite unconscious of the removal of the gold-leaf, and though it might possibly be unnecessary, he did not at present see his way to dispense with it. Further, he did not consider his technique perfect, and therefore his suggestion might be further improved upon.

The difficulty and responsibility of deciding whether to operate were duly discussed, but no new indications were arrived at. With every improvement the tendency is to increase the number of operations, and the constant danger of intracranial extension points in the same direction. On the other hand, such extension is rare, for most practitioners know of cases in which otorrhœa has lasted for years without inconvenience. I have known it to last forty years without any serious symptom. Nevertheless, a complete operation is a protection from the risk such a patient is always running, and Mr. Ballance's plan seems a distinct advance.

The exhibition of cases at the Medical Society on the clinical evenings is usually very interesting—much more so than many papers—though only a few lend themselves to reporting. At the last meeting there was a resection of intestine in a boy aged seven years; a case of urticaria pigmentosa in a boy aged fifteen months; cyanosis in a girl aged eighteen years, probably congenital, but without cardiac murmur. It was suggested as to this that perhaps the opening was too large to produce a murmur and the valves were normal, another suggestion being that the aorta arose on the left-hand side. The right ventricle seemed dilated. There was shown the heart of a boy aged fourteen years, who was brought to a former meeting, and who died suddenly eight days later. The left ventricle was hypertrophied and the aortic opening reduced to a slit. Another heart case was in a man aged twenty-two years, the heart-beat being on the right side in the sixth space, the stomach and the liver being also transposed. Two rather rare cases of rheumatism were present; one of osteo-arthritis in a girl aged eight years after several attacks of acute rheumatism; the other in a girl who had chorea followed by cardiac disease and embolism. A somewhat obscure case of tumor of the femur in a man aged twenty-nine years was thought to be osteitis deformans involving only one bone. Three cases of hernia due to or associated with abnormal descent of the testis elicited the mention of some other cases more or less similar.

Besides patients, appliances were shown, viz., a tourniquet to compress the artery in amputation of the hip-joint, but which has also been used in other operations; two jackets for aiding respiration in emphysema; one applies pressure continuously, the other intermittently. Both had been tried and improvement followed. The rival inventors can discuss their relative value.

AN APPENDICITIS OPERATION IN 1867.

To the Editor of the Medical Record.

Sir: In his excellent historical essay on appendicitis recently published, Dr. Edebohls says: "In his first case of operation (1867) for perityphlitic abscess resulting from perforation of appendix, Dr. Weber contented himself with cutting down as far as the fascia transversalis, allowing the abscess to open spontaneously through the wound thus made."

The case of L. H——, referred to, was the second operated on in this city by what was then known as the Willard-Parker method, and there was a feature in the progress of the operation which was of considerable interest to me and others at that time, and may be of interest even now, because the procedure then employed by force majeure, or accident, if you please, might be followed with advantage in suitable cases as a modification of the method usually employed in modern times.

In making the incision I was advised by one of the surgeons present to make it much nearer to Poupart's ligament than it had been my intention to do. Very soon I came down upon the large vessels and could feel and see the iliac artery pulsate. In fact, I had proceeded very much as if I had intended to tie the iliac artery. When I had gone so far and found that I was below the abscess and behind the peritoneum, I thought I had gone far enough; the gentlemen present were of the same opinion, and a drain was laid to the bottom of the wound; the greater part of it was left open. It was, indeed, to my great satisfaction and the patient's welfare that the pressure of the pus collected worked in the direction of the least resistance, and the abscess discharged within forty-eight hours after the incision through the wound made.

In all my other cases of appendicular abscess operated in the old way, I cut down through the abdominal muscles direct into the abscess cavity, but have often thought that my first experience had pointed a way to get at the appendix by a different route from the one in vogue, and have the advantage of avoiding the division of the abdominal muscular structures. It is long since I have practised surgery, but it seems to me it might be worth trying whether it be practicable and safe to cut down as far, tying the common iliac, and remove the appendix that way. Abdominal hernia, infection of abdominal muscles, etc., would then be readily avoided. With these few words on an ever interesting and important subject I leave the consideration of my proposition to the surgical confrères.

LEONARD WEBER, M.D.

ANTIPNEUMONIC SERUM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of February 24th, Dr. A. H. Smith, in replying to my letter which appeared in the MEDICAL RECORD of January 27th, refers me to his article in the "Twentieth Century Practice," vol. xvi., p. 122, wherein he "has discussed at length the claims of antipneumonic serum therapy." I am sorry that Dr. Smith's answer only implies that I had no knowledge of the existence of this article, and also that, in his opinion, antipneumonic serum is a remedy of such doubtful efficacy that he considered it not worth mentioning in his recent paper.

In justice to myself, I wish to state that at the time of writing the letter to which Dr. Smith now replies, I had read the aforesaid article in the "Twentieth Century Practice." In this article Dr. Smith gives an excellent historical sketch of the attempt at antipneumonic serum therapy, beginning with Netler (1888) and ending with De Renzi and Pane. He mentions as the latest achievements in this field the first thirty-two cases of De Renzi and the first five cases of Maragliano—all of which, by the way, are quoted from my first article on the subject (*New York Medical Journal*, May 7, 1898).

My surprise, therefore, was caused by the fact that Dr. Smith does not take into consideration in his recent paper the advances which have taken place in this field since the publication of the first successes of De Renzi and Maragliano.

As a matter of fact, however, a large number of successful cases with Pane's serum have been reported since then by Massolongo (Milan), by Cantieri (Siena), by Maragliano (Genoa), by De Renzi and Pane (Naples), and by many other clinicians. All the reported cases were of the gravest character, and the percentage of cures is enormously in excess of that obtained with the old empiric methods.

Professor Maragliano, in the closing lecture of the session of 1898, said to his students: "Taking the results of the past-year and those of the year before, I am becoming more and more convinced of the antitoxic power of Pane's serum, and of its efficient therapeutic action in pneumonia. All the cases treated with the serum were most severe."

Professor De Renzi, at the Congress of Internal Medicine held at Turin in 1898, said: "A case of pneumonia, no matter how grave, treated in time with a sufficient amount of serum, must surely recover."

For my part, I do not think that we can afford to ignore the testimony of these observers.

ANTONIO FANONI, M.D.

66 WEST TENTH STREET.

OUR VIENNA LETTER.

(From our Special Correspondent.)

VIENNA, February 13, 1900.

PROFESSOR SCHAUTA has been using some new instruments in his clinic this week. One, a needle devised by Joannesdu, of Budapest, for carrying wire, is large and hollow, curved like an aneurism needle, and in a case of ventral hernia in a stout woman with very thick abdominal walls seemed to be very successful. Another is a double hook for craniotomy, designed by Zweifel, of Leipsic. It looks like two of the Braun hooks fastened together, side by side, and is supposed to be so adjusted in the tissues; then the two handles are turned apart, thus turning the hooks at the other end from each other. Professor Schauta thinks that it would be of advantage were it not for the fact that the hand must be removed before swinging the hooks, thus leaving one in doubt as to whether the maternal tissues are not being lacerated; and for this reason he is not prepared to indorse it fully, although it is quick and effective.

The professor has sacrificed his beard to the cause of asepsis, but neither he nor any of his assistants wears gloves while operating. They scrub thoroughly with soap and water, then with alcohol and bichloride. He uses Schleich's method of anæsthesia—ether, chloroform, and petroleum—and says that in the two years he has employed it in his clinic he has never had an accident; the patient comes out of the narcosis much more readily, and the after-effects are not to be compared with those following the use of any other anæsthetic.

They are treating all the chronic retroversions by the so-called "Belastungstherapie," a method introduced here by Dr. Josef Halban, one of Professor Schauta's assistants. After emptying the bladder the patient is placed on a table in the dorsal position, and a colpeurynter smeared with vaseline is introduced into the posterior cul-de-sac and filled with 0.5 kgm. of quicksilver. This is left in the vagina for one-half hour, unless it causes pain, in which case a shorter time is allowed. This treatment is continued daily, gradually extending the time and the amount of the quicksilver until the patient tolerates 1 kgm. of mercury one hour. In thirty-five cases recently followed up by Dr. Halban the results have been excellent. In the chronic cases of para- or perimetritis, he uses it in connection with abdominal massage, or makes counter-compression with shot on the abdominal wall after Freund's suggestions. The advantages of using quicksilver in the vagina in place of shot, which Freund used, would seem to be that the mercury much more readily assumes the shape of the cul-de-sac and causes less pain—acting really much more like massage.

The Wertheim operation, of shortening the round ligaments by going through the anterior vaginal wall, is done in place of the Alexander whenever possible.

At a recent meeting of the Dermatological Society, Dr. Rudolf Metzenauer, first assistant to Professor Neumann, read a report of some interesting investigations he has been carrying on in cases of hospital gangrene, whereby he has succeeded in isolating a bacterium which they are not prepared to classify, but which he believes to be the bacillus of hospital gangrene. It is a large bacillus, about one and one-half times larger than the tubercle bacillus, stains readily with the Weigert stain, and is found not only in the gangrenous tissue where the staphylococci, etc., exist, but is plainly visible in the deeper tissues in which no other bacteria can be demonstrated. In a set of three hundred and fifty slides he has never failed to find it. He has not yet succeeded in growing a culture, but he believes it to be anaerobic.

Medically there is little of interest, influenza playing the most important part in the wards at present.

THE APPENDICITIS QUESTION.

To the Editor of the Medical Record.

Sir: Dr. J. S. Horner's interesting article in the Medical Record for February 24th, under the above caption, calls for further response on my part as a sort of spokesman. He says that "it is only a step from operating on a mild case because it is likely to become severe, to operating on a normal appendix because it is liable to become infected." What is a mild case of appendicitis? Is it one in which the round slough is about to cause a perforation, without premonitory symptoms enough to keep the patient in bed; or is it a case of safely ulcerating mucosa with such spasm of the muscularis of the bowel that the patient is screaming with pain? Will he please define for us "a mild case." I know only the pathology of appendicitis, and do not know a mild case from a dangerous one. The doctor says that we are to "operate in primaiy cases when circumstances arise which in the opinion of the physician make it justifiable." In the opinion of which physician? Does Dr. Horner not know physicians whose opinion he would not trust? I have been present at consultations in cases in which concretions and pus had already escaped through the wall of the appendix, and some of the consultants thought that they could still cure the patient with sweet oil or opium or salts.

We are to be guided by our knowledge of the pathology of appendicitis and not by the opinion of any one who has not looked at the lesion in any given case. The doctor draws a picture of a case "with everything apparently favorable for a mild attack," and quotes the conversation between the physician and members of the family, including the statement that if the physician is honest he will answer concerning operation: "No! The chances are ninety-nine out of one hundred that he will recover." I will give one thousand dollars to the West Pawlet school fund if such percentage statement is correct for appendicitis cases in that town. If such percentage statement is not correct, then Dr. Horner should be careful about going on record, for we have some pretty correct data for guidance.

I made a similar offer two years ago, when Dr. Terry, in the *New York Medical Times*, stated that he had cured forty-nine cases of appendicitis out of fifty-one by medical treatment. I offered to give the above-named sum to a public institution if Dr. Terry would simply state that he personally knew what had become of the cured cases, and if some of them had not since died of appendicitis or had not been operated upon. In answer to my offer a great deal was said about the bad taste of betting in order to settle scientific questions, but nothing was said about the bad taste of publishing misleading statistics for the guidance of physicians who were dealing directly with human life and human happiness. Dr. Terry finally admitted that he knew little about the outcome of some of the cases with which I happened to be familiar. I did not accuse him of dishonesty, but of untrained observation and of unscientific method. Dr. Horner says: "There has as yet been no reason of sufficient importance presented to the profession why a mild case should be operated upon." What text-books does the doctor possess upon the subject? It seems to me that several authorities have given explicit reasons.

The doctor refers to my published letters from a series of appendicitis patients, all of whom stated that they suffered less under surgical treatment than under any sort of medical treatment, and he likens these letters to the testimonies from irresponsible patients in the public press. Has he actually read the letters in question? They are published in the Medical Record for May 21, 1898, and are republished in the third edition of my book on the subject. These letters are worth reading in a genuinely critical way. Dr. Horner quotes me properly as saying that physicians must either tell the patient at the beginning of an attack of appendicitis whether it will probably be a mild or a severe attack, or else they must confess that it can only be told afterward; but he says that the same thing is true of typhoid fever, pneumonia, and scarlet fever. Very well! If a case of typhoid fever, pneumonia, or scarlet fever began at a localized focus of infection, which could be readily picked up between the thumb and finger and put into a bottle, most of us would come to our senses in a few years about the proper method of procedure in the treatment of these cases. Dr. Horner says that hospital medical statistics show an immensely heavier rate of mortality than physicians find in their private practice. Where are these private practice statistics? As a matter of fact, physicians are apt to speak out of memory, and hospital statistics are in black and white. That is the chief explanation for the difference. Not long ago I stated, out of memory, that I had not lost a case of general septic peritonitis in which the patients were treated by flushing out the peritoneal cavity with hot saline solution, and by intravenous saline infusion. My statement was honest in intention, as I believe the statements of most physicians to be; but on going over records later, I found that two patients had died after recovery from the acute symptoms, because the function of the bowel could not be restored.

Dr. Horner says that my rule of operating in acute appendicitis as soon as the diagnosis has been made is impracticable. That depends upon the locality. It certainly is impracticable in localities where the surgeons have not proven their ability to make the suffering rate, the loss-of-time rate, and the death rate in appendicitis less under surgical treatment than under medical treatment of any sort. It is practicable, and is practised by many physicians in localities in which the environment of the patient enables him to benefit by the progress that has been made in our comprehension of the whole subject of appendicitis.

Robert T. Morris, M.D.

58 West Fifty-sixth Street.

Cholelithiasis.—In a recent address before the Nottingham Medico-Chirurgical Society upon "The Dangers of Delay," Dr. A. W. Mayo Robinson expressed his opinions upon treatment of cholelithiasis as follows: (1) Seeing that statistics from various countries and by many observers agree in showing the frequent association of gall stones and primary cancer of the gall bladder and liver, it is desirable that cases of cholelithiasis should be submitted to surgical treatment at an earlier stage than has hitherto been the custom. (2) In all cases of tumor of the gall bladder, even if unaccompanied by symptoms, an operation should be advised, and the obstruction, usually a calculus, should be removed. (3) If these rules were followed, primary cancer of the gall bladder and extension to the liver would probably be less frequent. (4) If early operation in cases of tumor of the gall bladder was followed out, even if cancer had commenced, it could be caught in an incipient stage, when a cure by cholecystectomy, or even partial hepatectomy, might be reasonably hoped for. (5) An exploratory operation, even in a patient seriously ill, with a localized tumor in the gall-bladder region, is worth advocating, though malignant disease be feared, in the hope that the disease may be inflammatory, and so capable of relief. (6) If there are any secondary nodules in the liver, or if adjoining viscera are invaded, the operation had better be terminated as a simple exploratory one.—*British Medical Journal.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, February 20, 1900.

JOHN H. HUDDLESTON, M.D., CHAIRMAN.

Some Observations in Counting Blood Cells.—DR. A. H. GARDNER presented some results of such observations. The technique followed by him had been the use of a smear from the finger, hardened in alcohol and ether, stained, and then examined with an oil-immersion lens. In nearly every instance he had counted the number of leucocytes in a cubic millimetre, and had endeavored to make the observation about midday. He stated that the generally accepted proportion of the various cells were: multinuclear, sixty-five to seventy per cent.; lymphocytes, twenty-five per cent.; eosinophiles, 0.5 per cent. About one-fifth of the lymphocytes were usually of the large variety. The most interesting part of his work had been in connection with typhoid fever, eleven cases having been studied. In a case of typhoid fever reported in detail by the speaker, the largest number of lymphocytes noted had been sixty-five per cent., and this had been on the tenth day, while the smallest number had been thirty-one per cent., occurring on the twenty-first day of the disease. In another case, in which four counts had been made after the occurrence of a relapse, the highest number had been sixty-four per cent., and the lowest forty per cent. On one occasion he had counted sixty eosinophiles. It was noticeable in all these cases that by far the larger number of lymphocytes were of the small variety. Similar results had been observed in the other typhoid cases. In two of the cases there had been slight leucocytosis, and these were the ones in which the Widal reaction had been absent. In a case of Hodgkin's disease there were twenty-nine per cent. of lymphocytes, twenty-seven of which had been of the small variety. In a case of sarcoma of the pleura there was twenty-two per cent. of lymphocytes, of which eighteen had been small. In a case of æstivo-autumnal malaria there was forty-nine per cent. of lymphocytes, thirty-five of which were small, and three eosinophiles had also been found. In a case of tumor of the brain there were twenty-nine lymphocytes, twenty-eight being small, and there were also four eosinophiles. An interesting case was referred to—one of chronic alcoholism with ascites and pleuritic effusion, in which examination of the latter showed 4.3 per cent. of multinuclear cells, 1.2 per cent. large multinuclear cells, 13.4 per cent. small multinuclear lymphocytes, and eighty per cent. eosinophiles. The blood of this man showed thirty-seven per cent. of multinuclear lymphocytes, eleven per cent. being large, thirteen per cent. small, and there was also thirty-nine per cent. of eosinophiles.

DR. I. ADLER said that he was of the opinion that much could be done by studies of this kind toward elucidating many interesting clinical and pathological problems. It was still a moot question as to how the multinuclear lymphocyte was formed, and studies of this nature would help to solve this and similar problems. It also seemed to him quite probable that these studies would make it necessary to give up very largely the attractive but mechanical notion of phagocytosis. It was probable that leucocytosis, when present, was not so much the effect of phagocytosis and the elimination from the system of germs and effete matter, but rather a renewed activity of the blood-making apparatus.

Membranous Colitis.—DR. WILLIAM H. THOMSON read a paper on this subject. He began with the statement that it was to be hoped that but few physicians would be called upon to treat a case of membranous colitis at the outset of their professional career, for it would under such circumstances prove most discouraging to the youthful physician. These patients were apt to develop a train of vague nervous symptoms in addition to their abdominal misery. In no other complaint was the morbid self-consciousness of abdominal affections more marked. Many writers had been led to look upon the disease as primarily a neurosis. Chronic bronchorrhœa or a chronic gleet was never a neurosis. The neurotic theory of the etiology of membranous colitis was most unfortunate, as it led the physician in the wrong direction in regard to treatment. Microscopical examination of the membranes discharged from the bowel showed a structureless material, wholly devoid of clots, leucocytes, or other ingredients of an inflammatory exudate. The clinical symptoms were utterly unlike those of ulcerative colitis. For example, constipation usually preceded and followed membranous colitis, while diarrhœa was one of the characteristics of ulcerative colitis. Hæmaturia and albuminuria were not uncommon as temporary symptoms in membranous colitis. He ascribed these renal symptoms to the entrance of the bacillus coli into the blood through the diseased intestinal wall. All the sections of the colon were characterized by abdominal distress, with tenesmus or pain before and during defecation. One of the important etiological factors was direct irritation of the rectum; *e.g.*, by horseback and bicycle riding, and pressure from uterine fibroids. Perhaps the most potent factor was the habitual and prolonged retention of hard scybalous masses of fæces in the rectum. The first indication for treatment was to relieve the colonic symptoms proper. Nothing was so soothing to the tenesmus and the general abdominal distress as irrigation of the colon with decinormal saline solution at a temperature of 110° F. This irrigating fluid should contain five drops of oil of peppermint to the pint of water. The irrigation should be given with the Kemp rectal irrigator, and several gallons of the saline solution should be used. This irrigation might be used as often as once in twelve hours. Unfortunately such treatment was not curative. He believed that in small or alterative doses of castor oil the physician possessed a remedy which was distinctly curative in this affection. It was proper to give the castor oil in an emulsion, each tablespoonful of which would contain half a drachm of the oil. It should be given half an hour before, or more than one hour after, meals, and should be continued for months at a time. Another useful remedy was nitrate of silver, given in doses of gr. ¼ of the silver salt, combined with gr. ix. of turpentine, in capsules, three times daily. After a course of this medication for six weeks, sulphate of copper should be substituted for the silver salt, and should be given in doses of gr. ¼. Abdominal massage and outdoor exercise were useful adjuncts. As these patients were very apt to reduce the dietary unwarrantably, he advised that they should be told simply to exclude beans, corn, spinach, and the woody vegetables.

Mucous Colitis.—DR. WALTER MENDELSON read a paper on this topic. He stated that there were three prominent symptoms in mucous colitis, viz., (1) neurasthenia, (2) the passage of mucus in various forms from the bowel, and (3) the existence of abdominal pain. These, were the history of long duration, made up the clinical picture of mucous colitis. The three symptoms usually coexist, but any one might be present or might largely predominate. Practically all cases gave a history of neurasthenia, and, although it was not always marked, it was invariably present.

The intensity of the pain was variable in degree. It was very common for the pain and the desire to go to stool to come on very early in the morning. Not all of the patients had loose passages; some passed hard masses of fæces. The mucus was always separated from the fecal matter, and not mingled with it as in catarrhal processes of the bowel. The essentially nervous nature of this disease should be kept in the foreground. The cause of this disorder was to be found in those occupations which overstrained the nervous system, and hence it was far more common in women than in men, and was a disease of brain-workers as distinguished from other occupations. The disease was most common between the twentieth and forty-fifth year, but childhood and old age were not entirely exempt. Mucous colitis he would attribute to a perverted action of the intestinal glands, the result of a disturbed metabolism brought about by abnormal innervation. In the treatment the rule should be not to treat the bowel trouble as such, but to treat the individual. It was of the highest importance to improve the general nutrition by the combined use of rest and food. Some clinicians advised the use of unbolted flour, small fruits with seeds, and other irritating articles of diet, with the idea of thus stimulating the intestine to do its work better. In administering enemata he had rarely found it necessary to use the long rectal tube, and had ordinarily employed either drugs or decinormal saline solution. One or two quarts should be given daily at the same time each day. It should be retained for about fifteen minutes. Drugs played a very subordinate part in the treatment of this disease. Unless the patients were willing to give the necessary time to the proper treatment—usually several weeks—very little could be expected. The neurotic woman was usually cured, while the hysterical woman broke off treatment and relapsed again and again, and rarely recovered completely.

Report on Three Cases of Amœbic Colitis.—DR. H. R. A. GRAESER reported these cases. The first of these was that of a man who had never lived outside of New York City. In his stools the amœbæ had been found at every examination. At first no Widal reaction had been obtained, but about one week later this reaction had been present, and there had been abundant evidence that this man had also become infected with typhoid. He died one week later, but no autopsy could be obtained. The second case was that of a young woman who had eight or nine stools daily. At every examination of the stools, after the first one, amœbæ had been present. The patient had improved rapidly, and had left the hospital before being regularly discharged. The third case was that of a man, who had from eight to twenty stools daily. His blood contained no plasmodia, and the Widal reaction was negative. The first examination of his fæces showed many very active amœbæ, and many Charcot-Leyden crystals. At no subsequent examination were the latter present. The treatment with calomel internally and quinine locally seemed to have given the best results. The fæces to be examined for the amœbæ should be received in a warm vessel, and immediately examined on a warm stage in order to find the live amœbæ. The amœbæ in these cases very often contained red blood cells. In the formed fæces these amœbæ were most abundant in the mucus on the surface of the fecal masses. In every case of obstinate or chronic diarrhœa the stools should be examined for living amœbæ or other intestinal parasites.

Examination in Cases of Amœbic Colitis.—DR. HARLOW BROOKS presented a brief summary of the eight cases of amœbic colitis occurring in the fourth division of Bellevue Hospital since December, 1897. He had also observed four other cases in private practice of other physicians. Four of the patients had certainly been infected outside of this city. One symptom, not previously mentioned, was the very severe, cramp-like pain in the skeletal muscles, especially in the muscles of the calves. The cases had been benefited chiefly by the use of enemas, and a solution of quinine, 1 : 5,000, or a solution of nitrate of silver of the same strength. None of the cases, so far as known, had relapsed. The stools for examination should be received in a warm bed-pan, and if acid should be at once neutralized by the addition of sodium bicarbonate. A portion of the stool should be then poured into a warm, wide-mouthed bottle, corked, and sent at once to the laboratory for examination under the microscope, preferably on a warm stage. It was important to take the precautions mentioned, and to make the examination as soon as possible after the stool had been passed. In such specimens many of the amœbæ would be found in an active state. If the stools became acid or cooled, the amœbic movement would be destroyed. Unless the movement of the amœbæ could be seen, it was often most difficult to make a correct diagnosis. He had not found stained specimens very satisfactory. The specimens could be fixed as were blood specimens, preferably by heat fixation. They could then be stained by the ordinary Loeffler stain. The nucleus did not readily stain, while the foreign bodies adhering to or within the amœba stained readily, thus obscuring the amœba itself. Generally the number of amœbæ present corresponded to the severity of the symptoms. Amœbæ from the stools discharged shortly after having taken a quinine enema were usually motionless.

Duration and Prognosis of the Various Forms of Chronic Colitis.—DR. JAMES K. CROOK read this paper. He asserted that nature paid no heed to the artificial divisions of the intestinal canal so carefully drawn by the anatomists, one or more parts, or even the whole intestinal canal, being sometimes involved at once in the disease process. In chronic inflammatory states of the large intestine, with recognizable symptoms, the prognosis was naturally quite serious. The various types of colitis had been sufficiently described by the foregoing speakers.

DR. ROBERT T. MORRIS said that he wished to say a word in support of the theory that some of these cases of membranous colitis and mucous colitis represented a functional neurosis. Surgeons considered some of these cases coming to them quite curable. This was probably because of the special nature of the cases which they saw—namely, those having a recognizable and definite source of peripheral irritation. As he was speaking from memory and not from accurate clinical records, he could not state just what proportion such cases bore to the total. A common surgical cause was a loose kidney. He recalled one such case, occurring in a hysterical woman, in which after fixing the kidneys most of the symptoms had disappeared, and she had gained somewhat in weight. He felt sure that many cases of membranous or mucous colitis could be relieved or cured by attention to an enteroptosis as the underlying cause.

DR. SPENCER FRANKLIN said that he had treated a good many cases of tropical or amœbic dysentery, and, finding almost no result from internal treatment, he had abandoned it in favor of enemas given with the long rectal tube. His plan had been to flush out the colon with saline solution, and then throw into the bowel, almost daily for a week, four ounces of a solution of nitrate of silver having the strength of ten or twenty-five grains to the ounce. This treatment seemed to physicians here very heroic, and while he would advise giving, as a preliminary, a hypodermic injection of morphine, he felt that such extreme measures were perfectly justifiable in the severe cases met with in the tropics. Since he had adopted this method he had not lost a single case.

Dr. Adler said that in the German Hospital, of this city, it was the practice to examine every diarrhœal stool microscopically, and by this method it had been found that amœbic and protozoic or infusorial diarrhœa was very much more common than was ordinarily supposed. The zoölogy of the human bowel had been by no means exhausted, and the subject was much more extensive than was usually believed. He had seen many cases of amœbic colitis, and was thoroughly convinced that the tropical colitis was the result of an entirely different species of amœba. His experience would not lead him to be anything like so sanguine as was Dr. Brooks. He could not recall having permanently cured any one of his patients. Sometimes there would be a cessation for several months, or even for a year or two, yet even Dr. Graeser had shown that microscopical examination of the mucus of the bowel would reveal the presence of the living amœbæ. He had seen no real benefits in these cases from the internal use of salol or tannalbin, but calomel, given in large doses or in small doses, invariably killed the amœbæ and checked the diarrhœa. This good effect would last for a certain fixed time—perhaps a week or two—after the administration of the calomel.

Dr. William B. Graves exhibited a colon taken from a case of chronic mucous colitis. The man had been under his observation for fifteen years, and had died with some uræmic condition. The colon was very much swollen and narrowed in its diameter, and was adherent at the splenic junction. Its lumen was almost obliterated.

Dr. Harlow Brooks said that he had examined two caess of mucous colitis post mortem, with an entirely negative result.

Dr. William H. Thomson said that the changes found in this colon were quite characteristic of cases of chronic nephritis affecting the colon, and the antecedent condition might have been very different. It seemed to him that the mucous colitis described by Dr. Mendelson was identical with his own cases of membranous colitis. Every patient with membranous colitis would in time become neurasthenic. From careful notes he could say most positively that some of his patients had presented not the slightest evidence of neurasthenia until they had been sufferers for some time from membranous colitis.

Dr. Mendelson replied that the results of treatment had convinced him that the nervous element was the prominent though not the only one, and if it could be eliminated the intestinal affection could be cured. Many of the cases coming to him had lasted for a number of years, and the intestine had previously received assiduous attention, yet with little or no benefit.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, February 19, 1900.

Frederick Holme Wiggin, M.D., President.

Report of a Case of Rupture of the Perineum in Coitus.—Dr. R. Abrahams made this report. He stated that, according to a recently published article, medical literature contained only twenty-two recorded cases of a similar nature. His patient was a woman of twenty-six, who married in the latter part of December, 1899. Her previous health had been good, and she had never suffered from prolapse of the rectum, hemorrhoids, ischio-rectal abscess, or any inflammatory process in the perineum. At the first sexual intercourse the hymen had been ruptured, and a little blood had escaped. During the first six weeks of their married life, the couple cohabited six or eight times, and on the last of these occasions there had been a little pain and considerable bleeding attendant upon the act. These were regarded, as she had expressed it, as "the finishing touch to virginity," but the following morning she had been astounded to observe that fæces escaped not only from the anus but from another opening higher up. This had led to her consulting Dr. Abrahams. On examination, the external genitalia, the vagina, and the uterus had been found well developed and perfectly normal, but there was a complete rupture of the perineum as if it had been designedly made with a surgical instrument. Two fingers could be readily passed through the wound into the rectum, but careful examination had failed to reveal any recto-vaginal or recto-vulvar communication—only what might be called a recto-perineal fistula. The patient had become alarmed at the prospect of an operation for the repair of the rupture, and had disappeared from observation.

Dr. Edwin Gaillard Mason said that he had seen one similar case during his experience in St. Mary's Hospital. The patient was a young woman who had been married a few months, and the rupture had occurred during the first attempt at coitus. The hymen was exceedingly thick, and he had cut it away. The laceration had extended through the recto-vaginal fold. Between the time of the occurrence of the laceration and the operation for its repair sexual intercourse had taken place through the rupture.

Exhibition of New Devices for the Administration of Anæsthetics.—Dr. S. Ormond Goldan exhibited a bag fitted with a valve obturator, and also a simple apparatus for the administration of nitrous-oxide gas in conjunction with ether. It was devoid of valves, and it was possible to induce a perfectly normal nitrous-oxide anæsthesia without the admission of air. He also showed a device for administering the chloroform through a tracheotomy tube, and also a triple tenaculum which he had found very useful for preventing the tongue from dropping back while performing artificial respiration without proper assistance.

Dr. J. W. Draper Maury exhibited a modification of the S. S. White apparatus.

Discussion on Anæsthetics.—This was the special topic for the evening's discussion.

Selection of the Anæsthetic in Surgery.—Dr. John A. Wyeth opened the discussion by a consideration of the selection of the anæsthetic, considering, however, only the use of chloroform and ether unmixed. He said that during the first few years of his practice he had employed ether almost exclusively, and during this time had not failed to note the great irritation sometimes caused by this anæsthetic agent, and the great difficulty of inducing complete narcosis in alcoholic subjects without producing asphyxia. He had, therefore, been led gradually to make more and more frequent use of chloroform. At present, in about seventy-five per cent. of his operations he employed chloroform, either wholly or in some stage of the narcosis. In using chloroform he invariably injected beneath the skin one-fourth of a grain of morphine and $\frac{1}{150}$ of a grain of atropine about fifteen minutes before commencing the anæsthesia. These agents stimulated the heart, and allayed to a considerable extent the anxiety of the patient. He believed chloroform was dangerous chiefly to the heart, and that it was during the early stage of its administration that this danger was imminent. The depression of the heart, when observed at all, occurred almost invariably prior to the induction of complete narcosis.

Administration of Chloroform.—Chloroform should be administered with very great care, and only by an expert. In giving chloroform, he preferred to use the ordinary Esmarch's screen, keeping his finger on the pulse and watching the pupil for any sudden dilatation. If the patient gradually gave way to the anæsthetic and the pulse showed no interruption in its rhythm, he felt satisfied that the chloroform was having no unfavorable effect. The pulse might be rapid —120 or more a minute—or it might be as slow as 50 or 60 beats per minute, but these variations were not suggestive of serious danger so long as the heart beat regularly and rhythmically. If, however, a beat was lost here and there, or if two successive beats fell off in fulness, and then rose again in volume, it was always to him a signal which was to be respected, and he promptly withdrew the chloroform for a moment to note the effect. Should sudden pallor of the face occur, especially about the lips, on resuming the chloroform, he stopped the anæsthetic, and lowered the patient's head, preferably placing him in the Trendelenburg position. If the heart still showed resentment to chloroform, ether was at once substituted. If there had been no alarming symptoms from the first use of chloroform, he returned to it after having administered the ether for a short time. Another alarming symptom of the too profound effect of chloroform was the sudden and wide dilatation of the pupil. When this occurred, he always desisted from the use of chloroform anæsthesia. In his opinion, it was not proper to endeavor to bring the patient rapidly under the influence of chloroform. The free admixture of air was essential to safety. The average time for complete narcosis with chloroform was from fifteen to twenty minutes.

Ether Narcosis.—When ether was employed, he always used it with the Ormsby inhaler, or some form of inhaler which did not allow of the passage of the atmosphere directly over the inhaler and into the apparatus. The Allis instrument, or any similar form of open inhaler, seemed to him extremely objectionable because the passage of the atmosphere over the inhaler lowered the temperature within the inhaler and carried a chilled vapor into the respiratory passages, often exciting inflammation in this way. The introduction of a warm, moist anæsthetic vapor facilitated and modified the anæsthesia satisfactorily. In a series of administrations at operations in the Mt. Sinai Hospital he had proved that with the Ormsby inhaler the patient could be anæsthetized with ether and maintained under narcosis, and would come out of the anæsthetic more rapidly and with less irritation of the kidneys or other organs than by any other method of administration. It was well known that the elimination of the ether vapor by the kidneys was the cause of very considerable irritation of these organs. Of course, the greater the volume of ether in the blood, the greater was the volume that must be eliminated by the kidneys. Just here was observed one of the advantages of the closed inhaler—*i.e.*, the diminution in the quantity of the anæsthetic necessary for a given period of narcosis.

Ether and Chloroform Contrasted.—In the hands of a tyro ether was safer than chloroform, and this without regard to the condition of the patient, but in the hands of an experienced anæsthetist, and one who had studied his case carefully and had satisfied himself that the use of chloroform was justified, this agent was practically without danger. He preferred chloroform in all cases in which there were pathological changes in the kidneys, and in which heart lesions were absent. When the lungs were seriously involved, as by tuberculosis, gummatous tumors, or inflammatory changes, or when there was a moderate pleuritic effusion, chloroform was preferable. When, however, in any way the heart had become crippled, ether was the safer anæsthetic. For operations in the abdominal cavity, chloroform was preferable for the reason that vomiting was less likely to occur during and after the operation. He was especially afraid of chloroform in patients who had had repeated attacks of rheumatism, and in whom the action of the heart was weakened by serious valvular lesion, atheroma, or fatty metamorphosis. In alcoholic subjects chloroform was preferable because of the difficulties met with in securing profound narcosis from ether.

Chloroform Unsafe for Children.—In children, ether was, in general, the safer anæsthetic. He had been taught that chloroform was the better anæsthetic in this class of cases, but he had learned that in children under twelve years of age chloroform was not so safe as ether. He had seen death occur in a child of ten years, without a single danger signal, and when not more than one drachm of chloroform had been administered by an expert. Chloroform was especially dangerous in children who were poorly nourished or weakened by any dyscrasia. Particular care was necessary when the child struggled and made deep and rapid inspirations. Over the age of twelve years, in healthy subjects, he believed chloroform to be as safe as ether.

The Amount of the Anæsthetic.—DR. THOMAS L. BENNETT took up this topic. He stated that in his opinion many of the symptoms of prostration noticed after operation, and attributed to hemorrhage or shock, were really due to overstimulation from the use of an excessive amount of the anæsthetic. Many factors entered into the production of nausea and vomiting after operation, yet he was sure that there was a direct relation between these symptoms and the quantity of the anæsthetic employed. Asphyxia might result from an overdose of the anæsthetic agent, or from foreign bodies in the air passages. Syncope was invariably due to an overdose. Mucus, saliva, vomited matter, or blood might flow into the pharynx, and be carried into the trachea. Here it acted as an obstruction to respiration, and, as a result, the inspiratory efforts were greater, and these substances were drawn deeper and deeper into the lungs. Acute pulmonary œdema, in his experience, had been a rare complication of anæsthesia. The influence of anæsthetics upon the kidneys had received much attention, and all observers agreed that the chief factor was the quantity of the anæsthetic employed. The necessary amount of the given anæsthetic would depend upon: (1) The requirements of the individual patient; (2) the requirements of the particular operation; (3) the method of administration; (4) the administrator. Large, strong, energetic, wiry, neurotic, and intemperate patients, as a rule, required more than the average amount of the anæsthetic, while small, weak, lethargic, phlegmatic, and temperate people required less than the average amount. Many children about the age of puberty required an unusually large quantity of the anæsthetic. The amount would vary according to the nature, severity, location, and duration of the operation. Operations on the rectum, perineum, bladder, the eye and ear, and abdominal operations requiring severe and deep manipulations, all required a very deep narcosis. As to the method, he would say that when he had experienced great difficulty in securing ether narcosis by the open method he had succeeded quite rapidly when he resorted to the closed inhaler. There were two ways in which ether might be administered with a given inhaler, viz., (1) using a small quantity at short intervals, and (2) using a larger quantity at longer intervals. His personal preference was for the first method, just as he favored the drop-by-drop method of administering chloroform. On an average, about four ounces of ether would be required for the first hour, if the closed method was used, and about two ounces for the next hour.

Nitrous Oxide and its Modifications for Prolonged Surgical Operations.—Dr. S. Ormond Goldan read this paper. He said that in the use of nitrous-oxide gas for prolonged operations, the following precautions should be observed: (1) A sufficient quantity of gas should be at hand; (2) a hot cloth should be wrapped around the valve if the apparatus became covered with frost; (3) the patient's face should be turned on the side. Operations of delicate dissection, or where venous engorgement was undesirable, contraindicated the use of nitrous-oxide gas. The use of this gas was not contraindicated in abdominal operations, but it had been found necessary to flex the legs and thighs well in order to secure the proper relaxation. This was a point which had served him well, though he did not recollect having seen it mentioned in the books. It was undesirable to carry the anæsthesia to the production of clonic spasm. The time required for the induction of anæsthesia by nitrous oxide varied from thirty seconds to two minutes. About four gallons of gas was required in the average case to produce anæsthesia. Nitrous-oxide gas was an asphyxiating agent, although it also had anæsthetic properties, as was proved by its use with oxygen. When administered in conjunction with carbonic dioxide the patients often complained afterward of headache. To obviate this the inhaler should be opened occasionally, and then filled with fresh gas. For the administration of nitrous oxide and oxygen Dr. Hewitt's apparatus was generally employed. The effort was to give each patient as much oxygen as he or she would tolerate. The percentage of oxygen must be varied from time to time throughout the narcosis, depending upon the effect. The mask was kept constantly supplied, and the inhalation was continued uninterruptedly. This mode of anæsthetization required the greatest skill. As much oxygen as possible should be administered without interfering with the anæsthesia. Consciousness was almost immediately regained after nitrous-oxide anæsthesia. Sometimes there was intense headache for hours after its administration. Nausea and vomiting were also occasionally persistent for some hours. Hysterical attacks occurred at times after this anæsthetic. Anæsthetization with nitrous-oxide gas and oxygen was the most expensive of all the methods. In one operation lasting two hours, in which these gases had been administered in minimum quantity, the cost of the anæsthetic agents alone amounted to seven dollars.

Experience with Ethyl Chloride in General Anæsthesia.—Dr. James P. Tuttle read this paper, which was based on some experiments that he had made during the past three months with kelene, or pure ethyl chloride, as an adjunct to anæsthesia with ether. The first experiment had been made on November 15, 1899. The patient was a strong man aged forty-five years, having a fatty tumor on the border of the scapula. Insensibility to pain had been induced in four minutes, but the muscles had not relaxed promptly, and supposing that this could not be readily induced by kelene, the anæsthetist had been directed to change to ether. Complete narcosis had been induced so rapidly then that he had been at first alarmed. His next experiment had been on a case of hemorrhoids. For three minutes and a half kelene had been administered, and then, the cornea having become insensitive, ether had been given with the Ormsby inhaler, and complete anæsthesia had been induced in two minutes more. Since then he had adopted the following method: The kelene is sprayed upon the under surface of an Esmarch inhaler, and the spraying is repeated from time to time. As soon as the cornea became insensitive, ether was given by the Ormsby inhaler. In forty cases of which he had notes, the time required to induce anæsthesia had never exceeded seven minutes. As a rule, consciousness seemed to be retained up to the time of changing to ether. There was sometimes momentary spasm of the glottis at the time of beginning the use of the ether. The shortest time required for inducing anæsthesia had been three minutes and a half, and the longest seven minutes. Occasionally there had been a little struggling, but ordinarily the patient was conscious, and a reassuring word or two, explaining to him that there might be a momentary spasm or choking, was sufficient to prevent any struggling. He had asked a number of patients whether they had any recollection of the application of the ether cone, and in each instance had received a negative reply. In four cases the use of the ethyl chloride had proved unsatisfactory. In one of these it had been found exceedingly difficult to anæsthetize the patient with ether. None of these four persons was at all the worse for the kelene, and he felt sure that in none of these instances had the induction of ether narcosis been rendered more tedious or difficult by the preliminary use of the kelene. The average quantity of kelene employed had been between 10 and 20 c.c. He considered it important that the kelene should be kept in a closed graduated tube. He had seen no deleterious effects from this use of ethyl chloride.

Closed Inhalers Dangerous. — Dr. Hobart A. Hare, of Philadelphia, opened the general discussion. He stated that the physicians and surgeons in Philadelphia believed the best form of inhaler for both ether and chloroform to be the simplest one imaginable—the ordinary towel cone with a piece of absorbent cotton in the top of it, or an Allis inhaler for ether, and the folded towel for chloroform. Personally, he was very much opposed to the various forms of cumbersome apparatus that had been shown this evening. He was opposed to them because of their cumbersomeness, and because he believed much the same objections applied to tubes and bags in connection with inhalers that applied to tubes in infants' nursing-bottles. He believed a good many pulmonary accidents had occurred from the use of these bags and tubes in connection with inhalers. We were told, of course, that these things could be boiled and sterilized, but how often in private practice was this neglected when the physician or surgeon returned home tired out after a long and trying operation? He had seen a gynæcologist in Philadelphia use one of these bag inhalers, and had always been impressed with the idea that his patients were being anæsthetized primarily by the anæsthetic and secondarily by carbon dioxide, and thirdly, perhaps, anæsthetized or benumbed by taking into the system the effete material which it was known the breath was continually giving off. Physiological experiment had proved most positively that, after all, it was not the carbonic-acid gas which was given off from the lungs which acted so deleteriously in crowded rooms—as in the historical Black Hole of Calcutta—as the effete material expired. For these reasons he was of the opinion that an anæsthetic agent should be selected and used by itself without having its effect obscured and rendered more complex by the use of these closed inhalers.

Comparative Safety of Chloroform and Ether in Children.—He had been particularly interested in the title of Dr. Wyeth's paper because he believed it was a common fault to resort to the routine use of both ether and chloroform without carefully selecting the anæsthetic to suit the needs of the individual case. He had been greatly surprised to hear the statement by Dr. Wyeth that the use of chloroform in children was more dangerous than in adults, for he felt sure that medical literature would not support this assertion—indeed, it seemed reasonable to suppose that what might be called "the fresh heart" of the child could stand chloroform better than the heart of an older person. Again, ether seemed to him particularly objectionable in children because the delicate mucous membrane in the respiratory passages of the child was so much more apt to become inflamed as a result of the irritation set up by the ether.

Effect of Chloroform on the Heart.—He would also take issue with Dr. Wyeth in regard to the effect of chloroform on the heart. He did not believe that chloroform exercised primarily any very distinct depressing influence upon the left heart of an healthy individual. The explanation of the sudden circulatory failure which took place frequently during chloroform anæsthesia he believed was to be found, not in the heart, but in the vasomotor system. It was perfectly possible for a man to bleed to death into his own arteries. These deaths from chloroform, then, he would ascribe to vasomotor paralysis. A very large proportion of deaths from chloroform had occurred in the hands of dentists who had administered the drug to patients semi-recumbent or sitting up in a chair. In confirmation of this view, the speaker referred to a case seen by him in a private hospital of a colleague. The patient had suddenly become utterly pulseless, and the apex beat of the heart could not be felt over the precordium; indeed, a hasty auscultation had hardly revealed the heart sounds. Dr. Hare said that he had suggested in this emergency that the operator grasp the abdominal aorta. This had been done immediately, and at once the heart had begun to beat more naturally. This case seemed to him convincing evidence of the very important part played by the vasomotor system. When vasomotor failure did not occur, and still chloroform produced death, it did so, in his opinion, by paralyzing the sister centre of the vasomotor centre, *i.e.*, the respiratory centre. Dr. Hare said that he had studied this matter very carefully on animals for the Hyderabad commission, and had become thoroughly convinced that the primary effect of chloroform on the circulatory apparatus was to lower the blood pressure.

Atropine before Anæsthesia.—Again, surgeons innumerable had found that the use of atropine just prior to the administration of chloroform gave a more satisfactory anæsthesia. This was because atropine was one of the best vasomotor stimulants. The atropine more than the morphine was responsible for Dr. Wyeth's good results when these two drugs had been given prior to anæsthesia. The foregoing facts should impress another lesson, viz., that before anæsthesia is induced, or an operation performed, the limbs should be bandaged in a feeble patient. In urgent cases an abdominal compress should be applied with the same object in view.

Shock following Anæsthetization.—It had often seemed to him that the amount of the anæsthetic agent employed depended more upon the anæsthetizer than upon the anæsthetic agent or upon the patient. Some anæsthetists seemed to know almost instinctively when to add more of the anæsthetic, and when to stay their hand. The profession at large seemed to pay too little attention to the question of the shock produced upon the patient by the administration of an anæsthetic. This was a matter which could not fail to impress itself upon physicians rather than upon surgeons. He had repeatedly seen persons subjected to operations and recover apparently satisfactorily from them, and yet for many months afterward they had carried with them a distinct stigma resulting from the operation or the anæsthetic. Many women after such an experience do well for a short time, and then become vaguely nervous and out of health, and ultimately have to take the "rest cure."

Position of the Head and the Use of Tongue Forceps.—When one wished to be sure that air passed freely into the lungs, the head should be thrown forward in the position which it occupies in a trained runner. If the anæsthetic was properly given, the head maintained in this position, and the jaw properly manipulated, there would be seldom any occasion for the anæsthetizer to make use of the tongue forceps which so commonly decks the coat of the young hospital interne whose duty it is to administer the anæsthetic.

Avoidance of Nausea.—He believed in many cases the preliminary use of morphine increased the tendency to nausea and vomiting. He had discovered that if it was desired to avoid this nausea, whether due to the anæsthetic or to the morphine itself, it could be ordinarily accomplished by combining nitroglycerin with it.

Influence of Athletics and Fright.—He was of the opinion that nitrous-oxide gas should be used very carefully in any case in which there was atheroma, because this anæsthetic greatly increased the blood pressure. In the presence of valvular disease of the heart he would employ ether in preference to chloroform, and also in cases of fatty degeneration of this organ. On general principles, ether seemed to be a safer anæsthetic in young athletes than chloroform, because statistics showed very clearly that these persons were specially prone to accidents with chloroform. When engaged in laboratory work it had been recognized as a fact that strong, well-built dogs were very prone to die under chloroform, and that the better bred the dog the more susceptible was he to the lethal influence of this anæsthetic. Dr. Hare mentioned this amusing fact, he said, to emphasize the influence of fright, the highly bred dog exhibiting great fright before the anæsthetic had been administered.

The Effects of Different Anæsthetics Compared.—DR. R. COLEMAN KEMP continued the discussion, speaking of the effect of anæsthesia on the kidneys. He stated that, other conditions being the same, the secretion of the kidney varied with the quantity of blood flowing through the kidney, and by conditions affecting the general arterial pressure. Ether and nitrous oxide could be taken as the types of the vasoconstrictor anæsthetics; nevertheless, with ether the constriction of the renal vessels was entirely out of proportion to the constriction of the other vessels in the body—in other words, ether seemed to exert a selective action on the kidney. Moreover, in experiments on animals with these anæsthetics, the percentage of albumin was large with ether as compared with chloroform, and persisted for a long time. With the A. C. E. mixture the chloroform depression was noted and the typical effect of ether on the kidneys. The main objection to the Schleich mixtures, when given with the closed inhaler, was the occurrence of the chloroform heart and the ether kidney. Anæsthol contains chloride of ethyl, ether, and chloroform. The chloride of ethyl exerts a certain depressant effect upon the heart and upon the circulation. Nitrous-oxide gas and oxygen should be considered the safest anæsthetic, provided the patient was not atheromatous, and when kidney lesions were suspected or were known to exist. Chloroform, as regards the kidneys, occupied a close second position to nitrous-oxide gas. The mixtures possessed no advantages, since they combined the bad effects on the heart and on the kidneys, and one was ignorant of the actual amount of the various constituents taken into the system.

DR. FERDINAND HASBROUCK spoke from his personal experience as a dentist who had been administering nitrous-oxide gas constantly for over thirty years. He had administered the gas to nearly ninety-five thousand people, and had not yet lost a patient. He thought he was familiar with the case referred to by Dr. Hare, and believed it was one case out of one hundred and twenty thousand. (To this Dr. Hare assented.) Regarding the apparatus that had been exhibited, he said that it was very defective. The calibre of the tube was much too small to prevent the unpleasant suffocative sensation complained of by so many persons. He could administer nitrous-oxide gas to adults or children almost imperceptibly. As a rule, the sensations were pleasurable rather than disagreeable. He ascribed his good results to the use of a very large tube, and the old-fashioned Johnson inhaler. He had administered the gas for operations of one or two hours' duration—probably five hundred times for operations lasting one or more hours—and had never experienced any very great difficulty with it. He called attention to the fact that the valve in the iron cylinder containing nitrous-oxide gas might be broken without the knowledge of the anæsthetist, and thus leave him in a very unpleasant position.

A Large Mortality from Ether Anæsthesia.—Dr. R. H. M. Dawbarn called attention to the change of opinion which had taken place in New York City in recent years in favor of the more general use of chloroform as an anæsthetic. He believed that almost invariably when a man died under chloroform it was due to the ignorance of the anæsthetist. He made the statement that Dr. R. Coleman Kemp and Dr. William H. Thomson had records proving most conclusively that in the hospitals of this city about one patient in nineteen dies from ether anæsthesia. The speaker said that in the last ten years he had not had a single death from suppression of urine or from ether pneumonia after ether anæsthesia, and he attributed this largely to the use of a simple modification of the Clover inhaler. The breathing over and over again of the same ether in such an inhaler prevented chilling and undue irritation of the respiratory passages. Undoubtedly it produced a carbonic-acid anæsthesia, but so eminent an authority as Dr. H. C. Wood, of Philadelphia, had expressed his conviction that such anæsthesia was not injurious. The modified Clover inhaler to which he had referred could be cleansed in a moment—certainly in much less time than was required for cleaning the Allis inhaler. For the last ten years he had almost always given prior to anæsthesia gr. $\frac{1}{150}$ of atropine and gr. 1/6 of morphine, with a little whiskey. This medication reduced the quantity of the anæsthetic required, and certainly reduced, and sometimes annihilated, the element of fear.

Ether Gelatinizes Acid Urine.—Dr. J. A. Bodine referred to the observation, made some years ago by Dr. Andrew H. Smith, of this city, to the effect that when acid urine was mixed with ether in the laboratory it would gelatinize after a time, but that this did not occur when the urine was alkaline. This suggested the possibility, which seemed worthy of further study, that if the precaution was taken to have the urine acid before giving ether, the effect on the kidney might be less dangerous.

Fright an Important and Dangerous Factor.—The speaker laid great stress on the element of fright and apprehension concerning the administration of the anæsthetic, and referred to a case occurring in the practice of a surgeon in New York City, in which death had occurred just before the administration of the anæsthetic had been begun. In this person the autopsy revealed all the vital organs in a normal state. Because of this fright before anæsthesia, he favored the administration of a moderate dose of morphine. The reason that chloroform was relatively safer in obstetric practice was that the woman looked upon parturition as a natural process, and welcomed the anæsthetic as a relief from the pain. Future research regarding anæsthesia should be directed toward studying the effect of the anæsthetic upon the blood, as the field of pure clinical study of anæsthetics had been nearly exhausted.

A Simple Home-Made Ether Inhaler.—Dr. A. Ernest Gallant spoke of the important and responsible position of the skilled anæsthetist, and contrasted the usual fee which he received with that demanded and received by the operating surgeon. He advocated allowing the patient to hold the ether cone; the additional time required would be more than compensated for by the diminution of fright. His method of using the Allis inhaler was to remove the bandage from the frame, to cover the lower portion of the frame with a layer of absorbent cotton retained by slipping a rubber elastic band over the frame, and then loosely to fill the frame with gauze. The ether cone used and recommended by him could be readily made by any one at home, the frame being made from a piece of ordinary stove-pipe, tin, or galvanized iron leader pipe, three inches in diameter, and three and a half inches long, or even from a heavy piece of cardboard. If the latter was used, it should be wetted on one side to make it flexible, and then bent to an oval shape. The gauze was to be adjusted over the end, and a newspaper, folded eight inches wide and wrapped in a towel, was wound tightly around the frame, both ends being left open. The loose gauze having been put into the frame, the inhaler is ready for use.

Effect of Chloroform after Nitrous Oxide.—Dr. J. W. Draper Maury said that he understood that in Germany the custom was not to give chloroform by the drop method, as had been stated, but by saturating the mask with the chloroform. If nitrous oxide was followed by chloroform it almost always induced vomiting, and not infrequently the effect of chloroform on the heart after the use of gas was deleterious.

Schleich's Mixtures Commended.—Dr. M. L. Maduro spoke favorably of the Schleich mixtures, and in this connection cited the experimental work of Dr. S. J. Meltzer. This investigator claimed that the petroleum ether was the dangerous constituent, though Schleich denied this. The work of Drs. Kemp and Thomson was interesting, but was more than offset by the results of experience, as abundantly proved by the statements that had been made in this discussion.

Dr. Parker Syms spoke with great earnestness in favor of the growing tendency to turn over the administration of anæsthetics to those specially trained for this work.

Dr. Emil Mayer brought up the question as to when consciousness ceased, and the important bearing which it had upon the conduct and conversation of those present in the anæsthetizing-room.

Dr. Hare emphasized the fact that the dose of the anæsthetic which the patient got was not that quantity which was put upon the towel or mask, or which was breathed, but the amount which was absorbed. For this reason, if the patient breathed in one ounce of ether in a closed inhaler, and breathed it over again ten times, there was very little difference in the effect upon that patient, as regarded the quantity of the anæsthetic, from giving a good many ounces of ether on an open inhaler. In his opinion, the reason that the parturient woman could take chloroform so much more safely than others was because the pain stimulated the abdominal vasomotor centres. In conclusion, he advised that a careful selection of the anæsthetic should be made for each case.

Dr. Goldan, in closing, said that he always made it a practice to sterilize thoroughly his bag inhaler each time. Regarding the physiological experiments of Drs. Kemp and Thomson, he would say that their results were decidedly at variance with clinical experience, for certainly it was rare to find bloody urine or suppression of the renal secretion after etherization. Chloroform should never be given immediately after nitrous-oxide gas; if it must be given, ether should be used as an intermediate agent.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 3, 1900:

	Cases.	Deaths.
Tuberculosis	193	171
Typhoid fever	7	3
Scarlet fever	160	23
Measles	818	33
Diphtheria	262	54
Laryngeal diphtheria (croup)	21	13
Cerebro-spinal meningitis	0	7
Chicken-pox	17	0

A Resected Coil of Small Intestine Twice Perforated by a fragment of bone 4 cm. long by 1.5 cm. wide was demonstrated by Büdinger at a meeting of the Gesellschaft der Aerzte in Vienna on October 20, 1899. The patient had presented himself on account of a painful swelling in the right inguinal region, which upon operation proved to be a collection of foul-smelling pus. — *Klinisch-therap. Wochenschrift*, 1899, No. 43.

Precocious Dentition.—Heard (*British Medical Journal*, December 2, 1899, p. 1543) reports the case of a girl, born at seven and a half months, labor being induced prematurely on account of a justo-minor pelvis. The infant was perfectly normal and healthy in every way, but the two lower central incisor teeth were visible under the gum. These cut through within a few days after birth, the right on about the fourth and the left on the fifth day. In a few days an abscess began to form, and the teeth to loosen. It was decided to extract the teeth, and a distinct effort was required in the operation. They were typical milk-teeth of a whitish color. For some time after the lateral incisors appeared there was a gap, but this subsequently closed.

A Story of Sir William MacCormac.—Here is a story of Sir William MacCormac, which strikingly illustrates his well-known kindliness of disposition and willingness to assist in any emergency. On the night of the terrible explosion which occurred some years ago at Shoeburyness, when Colonel Fox Strangeways and eight others lost their lives, Sir William was telegraphed for at a late hour and hurried off to Fenchurch Street, where, after no little difficulty, he was provided with a special train. By a stroke of luck a well-known journalist had also "caught wind" of the catastrophe, but on reaching the station he discovered that the train had gone. Seeing the preparations that were being made for the "special," he boldly approached Sir William, and was invited, to his astonishment, to share the saloon. At the station a brougham was waiting for the famous specialist, and recognizing that unless he continued to stick close to his fellow-traveller he would have all his journey for nothing, the reporter hit upon another expedient. With a glance at the doctor he took possession of the two cases of surgical instruments, and with one in each hand he mounted the box and sat beside the coachman. At the station hospital his entrée was unchallenged, as he was assumed to be the great surgeon's servant. Having written a hurried account of the disaster and secured a list of the killed and injured, he promptly roused the telegraph clerk from his bed and was thus able to send his office in London a full and exclusive description of the whole affair. Naturally he still retains the liveliest recollection of the services rendered him by the man who is now at the Cape.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended March 2, 1900:

SOME POINTS IN THERAPEUTICS OF HEART DISEASES.[1]

By W. H. THOMSON, M.D., LL.D.,
NEW YORK CITY,
PHYSICIAN TO THE ROOSEVELT HOSPITAL.

In diseases of no other organ do the indications for treatment differ so widely as they often do between different conditions in both the acute and in the chronic affections of the heart. In the limits of this paper I can only point out the salient features in these contrasts, with the reasons why the heart in its disorders at one time calls for one class of remedial measures, and for a wholly different class at another, so that this organ should be regarded as the last in the body whose disorders can allow of any routine fashion of treatment.

First, as to the acute disorders. The great majority of them are of an inflammatory character. But it is a serious mistake to regard them as always or predominantly so. In many instances, as in diphtheria, the danger to the patient is not from inflammation, but from a parenchymatous myocardial degeneration. A similar danger often arises in the hearts of children during attacks of the exanthemata, in pertussis, and in pneumonia, in which the deaths are due primarily to the involvement of the heart, which may be fatally weakened by the toxins of these infections without giving any auscultatory signs of a carditis. Even in the carditis of rheumatism, a specific softening and consequent distensibility of the myocardium generally take place, which may be revealed on physical examination only by percussion; while on the other hand there may be evidences of general failure in the circulation whose gravity should be fully appreciated, though the auscultatory signs be relatively little marked. Overstrain also may produce an acute condition of dilatation with its symptoms and indications for treatment differing from any of those above mentioned, and this may occur not only in healthy hearts from undue muscular stress, but also from injudicious exertion in convalescents from a prolonged fever.

First, then, I will allude to the acute inflammatory states. The condition, then, is one of great excitement of the viscus. Our chief complication on that account arises from the fact that normally this organ rests the least of any other in the body. The two layers of the pericardium rub against each other in health seventy times and more in a minute, in pericarditis a hundred and twenty times and more. Could the slightest inflammation in any other part of the body get well readily if it was moved as often? Nevertheless rest is one of the most imperative indications in all inflammations, and none the less so in the case of the heart. Rest from over-action must invariably be the first aim in acute carditis of every form. This truth cannot be emphasized too strongly. When the heart is beginning to fail in acute cardiac inflammations, as the pulse, dyspnœa, and other signs of circulatory embarrassment develop it is from an over-fatigue which in the majority of cases will only be aggravated by administering heart stimulants. The recognition of the exact indications for treatment is then of the supremest importance, and I would define them thus:

With a febrile temperature, cardiac pain either sensible to the patient or elicited by pressing upward during expiration under the left costal arch, with hurried breathing, rapidly rising pulse, and, on auscultation, disturbed rhythm with or without murmurs, the treatment should be as follows: Leeches to the precordium, afterward constant poultices of flaxseed meal made with extract of hamamelis, and laudanum poured on just as the cataplasm is applied, and then covered with oiled silk and that part carefully so covered without a single exposure night and day. This is not a mere minor detail, for I have seen an acute pericarditis fatally aggravated by a medical teacher baring the chest of the patient in a cold ward for upward of an hour while a large class of students listened to the interesting friction sound. While there is no vascular connection between the circulation of the skin and the blood-vessels of internal viscera, there is the most intimate vasomotor association between the nerves which control the blood-vessels of the viscera and the cutaneous nerves of the corresponding skin areas above them. Cold applied suddenly to the skin of the abdomen will check a post-partum hemorrhage, not by the cold striking in, but by the same blood-vessel constriction occurring within, through reflex vascular action, which the cold causes in the blood-vessels on the surface. In disease this mutual sensitiveness becomes heightened in two ways. The internal irritation causes a hyperæsthesia of the cutaneous nerves, which reacts all the more upon the vasomotor nerves of the internal viscera. Let a cold hand be suddenly laid on the precordium in health and it will cause the heart to bound. In a carditis the heart is all the more sensitive to such an impression. So with a phthisical localized pleurisy at one lung apex, the application of a cold hand will cause the patient to give a cough, while the same application to the chest over the sound lung will not. I have used this fact for diagnosis in physical examination. Owing, therefore, to this relation between the skin and the heart, I always am particular to use vascular sedatives to the precordium as a preventive as well as a remedial measure when acute carditis is impending or present; and besides what I have recommended by the protection of moist heat, I would add that no vascular sedative is so potent in acute inflammation as topical blood-letting. This is wholly through the surface nerve impression of the bleeding, and this fact is illustrated in a great variety of other conditions. A leech applied at the sternal notch will often surprisingly relieve the agonizing dyspnœa of a thoracic aneurism; a few leeches to the epigastrium will as surely check the vomiting of acute gastritis; leeches on the mastoid will also likewise relieve the pain of meningitis, etc.—all of which examples can be explained in no other way than that of the production of reflex nerve sedation. In acute rheumatism, which is so common a cause of cardiac inflammations, the tendency to sweating and consequent easy surface chill should be guarded against from the beginning by discarding sheets and directing the patient to have only underwear of flannel, and to lie between blankets throughout his illness.

---

[1] Paper read before the Jersey City Practitioners' Club, February 13, 1900.

One medicine takes the lead of all others in acute inflammations of the heart, and that is aconite. It is the ideal heart sedative in all such conditions on account of its prompt alleviation of cardiac pain and consequent irritation, and secondly on account of its specific action of slowing the heart beats. While the salicylates have proved invaluable in diminishing the pains of the acute arthritis, it must be confessed that they have wholly failed as preventives of rheumatic carditis. In fact I am certain that the old treatment with alkalies showed better results, as far as involvement of the heart is concerned, than does our experience to-day with the salicylic salts. But a steady employment of aconite pushed to producing its specific effects upon the pulse will often change marvellously for the better the whole clinical aspect of the case. This is shown very strikingly in some of the acute exacerbations of chronic heart disease. We repeatedly see cases admitted to our hospital wards with the worst conditions of general anæmia and intense dyspnœa, and then find the patients greatly improve without any medicine, evidently simply from rest in bed. Now, this common experience is explicable only by assuming that the dropsy and the pulmonary engorgement with hydrothorax are largely due to the heart failing from fatigue, and then recovering measurably from this weakening fatigue by rest in bed. But on the same principle I have again and again in these chronic cases stopped the administration of heart stimulants and substituted aconite, with an immediate change for the better in the gasping for breath and in the progressive increase in the pulmonary œdema. The indications here for giving aconite rather than digitalis, etc., are a strong laboring heart impulse and a rapid pulse. The same recommendation for aconite may be given in all cases of rapid pulse with distinct cardiac pains—in other words, when the evidence is plain of an irritable heart on account of causes directly traceable to intrinsic cardiac irritation, whether from the effects of previous inflammation or from over-strain. On the other hand, a quick pulse with high tension is not uncommonly the beginning of chronic heart disease from primary kidney disease. In this case veratrum viride is much better than aconite, owing to its specific dilatation of the arterioles, as well as to its slowing effect upon the heart.

Very different from the indications furnished by acute carditis (including in this term its three forms of endo-, myo-, and pericarditis) are the conditions presented by acute parenchymatous degeneration. Thus the toxin of diphtheria is one of the most powerful proteolytic poisons known. It digests and dissolves living muscular tissue more powerfully than pepsin dissolves the muscular elements of food. Thus the living heart begins to fall to pieces under its influence, and to this is added a like degeneration of the heart's great adjuvant in the circulation, namely, the muscular layer of the arteries. A very striking fall in blood pressure, therefore, takes place, which goes on progressively increasing till death, as has been conclusively established in experiments with this toxin on animals, as well as clinically in the human subject. In striking contrast, therefore, with the flush of acute rheumatic carditis, a surface pallor is the characteristic hue of these patients, quite different also in its way from the bluish pallor of carbonic-acid poisoning. We often note the same pallor, with its accompanying rapid, small, and irregular pulse, to result from other toxins of the exanthemata. Now, there is one drug often mistakenly administered in these conditions of heart weakness which is extremely mischievous, and that is digitalis. It is frequently prescribed with the idea that it is a heart-muscle tonic, and that, therefore, whenever we have a weak heart, we at once should give digitalis. But this term "tonic" is one of the vaguest terms current in our therapeutics, and that is saying a great deal. Thus we read of arsenic being a tonic, also iron, cod-liver oil, electricity, a cold bath, and a sea voyage. Anything, in short, that does good is called a tonic, the original conception evidently being derived from "tone" in music, as when the relaxed strings of a violin or of a piano are tightened or toned up. But vague terms lead to the loosest kind of practice, and what we need is to form very definite ideas about the specific action which we are aiming for under the term tonic. Now, the action of digitalis upon the heart is to throw its walls into an irregular kind of cramp. The heart, under its influence, has a mottled or nutmeg-like appearance, from the white, anæmic, contracted bundles compared with the more red, non-contracted neighboring strands. The general effect of its action, however, is to diminish the size of the heart's cavities. The drug, therefore, is of the greatest service when the heart walls are over-dilated and too much residual blood remains after each systole from inability of the dilated cavities to contract strongly enough to expel their contents. Cramp the heart walls to one-half the abnormal width and the heart systole then will work to much greater advantage, on an easily understood mechanical principle.

But here comes the important fact about digitalis, that in order to produce its contractile effect it must have a more or less normal muscle fibre to work upon. It is utterly powerless with degenerated heart muscle, whether it be in fatty degeneration or in the parenchymatous degeneration of diphtheria, or by the weakening of the fever toxins as in typhoid fever. Not only is it then powerless, but it is actually harmful from its cramping rather than stimulating effect upon the heart's action. I have seen the utmost distress caused by it in diphtheria, especially in a case which I shall never forget. But to illustrate my meaning I shall cite only one case, and that in an adult. He is a copper-mine magnate. After thirty years' active life spent in working copper mines which are situated at an average level of six thousand feet above the sea, he began to be very short-breathed. After some two years of increasing dyspnœa, accompanied by a cough ascribed to bronchitis, he had a sudden attack of pulmonary congestion which nearly terminated his life. He came on East and was seen by several medical consultants, who all agreed as to the diagnosis of great cardiac dilatation, without either valvular disease or general endarteritis. Again and again digitalis had been prescribed for his heart dilatation, and each time his symptoms were so much aggravated after taking it that he came to know digitalis by its effects in bringing on cardiac distress. When called to see him, I asked him if there was not a good deal of arsenic given off in the fumes of his smelting-works, among which works he was accustomed to be constantly going about on his daily rounds of inspection. "Oh!" said he, "arsenic lies around there like hoar frost!" Now, percussion showed the heart to be enormously dilated; no heart impulse was anywhere palpable. The pulse was extremely irregular, but there was no valvular leakage, and not a trace of œdema anwyhere. Arsenical fatty degeneration of the heart, with passive dilatation favored by high altitude (with some similar degeneration of the liver), was my diagnosis of the etiology of his cardiac condition; all digitalis was stopped and other remedies were prescribed, with the result that not only has he been able to lie down and sleep for eight hours as he had not done for two years, and also to attend copper-mine speculations in Wall Street, but he had a fall on the icy pavement five weeks ago in which he was knocked senseless and broke two ribs, without any more serious results following than if he had a normal heart.

In the heart weakness of diphtheria, instead of digitalis or its congener strophanthus, we ought to push the administration of alcohol to its utmost limits, with strychnine, caffeine, and, above all, the hypodermic injection of camphor in sterilized oil, in dose of gr. viii. of camphor to ♏ xx. of sterilized oil, repeated p.r.n. These remedies are also indicated in rheumatic conditions when the heart is beginning to fail. When, therefore, to stop aconite and the use of the other sedatives above mentioned as so valuable in acute carditis, and change to the stimulant class instead, is a proper question, and the answer is, when the heart is beating feebly instead of strongly, and when the feet are beginning to be no longer hot but cold.

The chronic sequelæ of acute endocarditis form too extensive a subject to permit me to do more than allude to some of their aspects. In the first place, after the beginning of convalescence from a severe rheumatic attack it would be greatly to the future advantage of the patient if he should be kept in bed for at least two months, especially in the case of children. When we consider that the rows of small vegetations along the edges of the valvular flaps act as so many irritating foreign bodies, like the granulations on the eyelids in trachoma, we have the explanation of the progressive involvement of the valves which we find a year afterward, with increased incompetence or constriction from the increasing fibrosis due to chronic inflammation. Prolonged rest and continued administration of aconite afford the greatest safeguards against the supervention of an irremediably damaged heart. The sequelæ of acute pericarditis, on the other hand, may be either wholly unimportant or the most distressing of all results of a cardiac inflammation. This last condition is when in addition to pericarditis we have peri-pericarditis as it may be termed, in which the inflammation extends beyond the pericardium so as to leave it finally attached to the sternum, ribs, and pleura. These consecutive adhesions prevent the heart from contracting fully in systole, and the most terrible dyspnœa may follow, with general valvular incompetence and dropsy. Inspection shows this state of things by actual recession occurring between the ribs during the systole. I speak of this condition mainly to emphasize the great relief which follows on the firmest strapping of the left chest, which approximates the ribs and lower end of the sternum to the laboring heart and prevents their undue external pull upon its walls. In all such cases for the frequent cardiac pains (which pains also often torment patients for months after acute endocarditis before good compensation is established), belladonna is of much service from its specific action in all disturbed conditions of rhythmically acting muscular fibre, by allaying spasm and restoring normal rhythm. Belladonna is thus often very beneficial in mitral stenosis.

The greatest contrasts of cardiac therapeutics, however, meet us in the treatment of chronic diseases of the heart which begin later in life than most instances of acute carditis. We may take for illustration such a case as the following: A man who has led an active, though meanwhile physically sedentary, business life, consults us for a shortness of breath, which he has noticed more or less for many months, but which lately is growing much worse. His complexion is quite significant; face full and irregularly mottled, with a decided yellowish paleness underlying a superficial reddish coloration of the cheeks. The forehead is often greasy. While he is speaking to us we notice that he has to take one or more inspirations before he finishes a sentence. He then may complain of nothing else about his breathing, but his mind has become sluggish or forgetful, and he is much troubled with gastro-intestinal flatulence and with disturbed sleep. We examine his heart and find that the cardiac impulse is very feeble or scarcely to be felt at all. There are no valvular murmurs, but the first sound at the apex is often a prolonged rumbling, while the second sound at the base may be too clear. His pulse is weak or ill sustained, and sometimes on exertion it intermits a beat or two. This man may die suddenly, and his autopsy may show no valvular disease whatever, but the aorta may be lined with atheromatous patches and the coronary arteries be found narrowed by a similar condition in them, while the heart walls prove to be the seat of extensive myocardial degeneration. Now this form of heart disease is by no means uncommon. My experience tells me that myocardial degeneration is one of the commonest and most efficient of all causes of failure of compensation in the heart diseases of patients after middle life, and that it precedes valvular incompetence in a large proportion of them. We meet them afterward with general anasarca, pulmonary œdema, mitral and tricuspid murmurs, etc., and put them down as cases of chronic valvular disease, when in reality the valvular incompetence and the arrhythmia and general dilatation are all secondary to a primary slowly developing change in the nutrition of the heart walls themselves, long unrecognized because there were no murmurs present. The first question which I ask myself, therefore, in such cases is, how long this patient's heart has been weak in its stroke, and not how long has he had valvular trouble of this kind or that, and the first question then to elicit from the patient is, when did shortness of breath first attract his attention on going upstairs or while walking against a wind? Then should follow a careful examination of his arteries and of the skin, such as whether the skin of the abdomen is chalky white and cannot be reddened by friction or by drawing the finger-nail upon it.

In the treatment of such cases of chronic heart disease I may mention the following points: First, every organ of the body which has to do with nutrition must be called upon to do its share to help the laboring heart, and if any of them are out of order they must be set to rights as a special part of the treatment of the heart disease; for every influence or condition which affects these injuriously constitutes by so much a factor of the cardiac trouble. In other words, we must not think only of the heart now. In this connection come, first, the effects of portal stasis. Gastric and intestinal flatus alone, without and still more with ascites, greatly embarrasses the heart, both mechanically and through its nervous relations. This flatus is due to fermentation in the alimentary canal, owing to readily understood causes. Gr. x. of sodium benzoate t.i.d. are helpful against this complication. Sodium phosphate, ʒ ii., dissolved in a tumblerful of quite hot water and sipped slowly, should be taken every morning. A blue pill, once every four nights, with half an ounce of the sodium phosphate the next morning, is a remedy I would not like to do without in such cases, and I have kept up this mercurial laxative for months together with the most striking benefit. When the kidneys are sluggish, whether albuminuria be present or not, there is no diuretic which will equal daily flushing of the bowels with three or four gallons of decinormal saline solution, at 110° F., by means of Kemp's rectal irrigator. It is now that digitalis is of such inestimable service in cases of dilatation subsequent to hypertrophy, with mitral regurgitation, ascites, hydrothorax, etc., but no clinical fact I think is better established than that in these conditions mercurial laxatives are the most effective adjuvants to this drug. I prefer in a new case to begin with full doses of a half ounce of the infusion of digitalis every three or four hours for the first two or three days, and then substitute for it afterward thirty drops of a mixture of equal parts of the tinctures of digitalis, strophanthus, and nux vomica. Always with each dose of digitalis nitroglycerin should be given to obviate the arteriole constriction which digitalis causes, and as soon as the digitalis beigns to disagree with the stomach its administration should be promptly intermitted. When neither digitalis nor strophanthus is well borne, a very good pill may be given instead, of sparteine sulphate gr. i., powdered squills gr. ss., caffeine citrate gr. iss., and strychnine gr. $\frac{1}{30}$. In quite a number of these cases, which at first sight might seem to indicate clearly the administration of digitalis, this drug fails altogether, or, after being apparently useful for a while, it loses its effect and causes much gastric disturbance instead. There can be little doubt that in such instances the myocardial degeneration has advanced too far for digitalis to be of any service, but fortunately we are not by any means left without other remedies.

The most important part of my subject, however, I have left to the close of this paper, and it is this, that the physician should not forget that all nervine medicines such as digitalis, strophanthus, nitroglycerin, strychnine, caffeine, sparteine, and the rest can never be other than temporary makeshifts. All that they can do is to relieve symptoms, and that only for a while. They may be of great service in warding off immediate dangers, and as adjuvants to the real remedies which act upon nutrition; but if a progressive degenerative process is going on, they are powerless to cure it. I am sure that one of the chief reasons for ultimate failure in the treatment of many chronic heart diseases is to be found in too great a reliance on such drugs. Permanent improvement is to come from other agents and measures which restore nutrition rather than stimulate function.

The first of these which I would mention is fresh air. If we are to have sanatoria for treating tuberculosis by fresh air supplied continuously night and day, I would advocate a similar aim, still more demonstrably applicable, for the prevention and cure of chronic heart failure. Throughout the whole animal kingdom muscular power invariably is found to be directly in proportion to the activity of the respiration, that is, to the amount of oxygen consumed. If we could breathe from every part of the body as insects do, instead of by one localized breathing apparatus, the muscular power of a man might be like that of a flea, and, as Huxley calculated, one man then could move Newgate prison across the street. Every muscular function in the human body is weakened by sedentary modes of life, because in such life breathing is lessened. But whereas surgeons deal chiefly with the skeletal or so-called voluntary muscles, we physicians should remember that for us general muscular weakness means, to begin with, weakened bronchial muscles; and therefore fresh air, or open air in summer, is one of the best things for chronic bronchitis and emphysema. Muscular weakness also means gastric and intestinal atony; witness how chronic constipation ceases after two weeks' camping in the woods. Muscular weakness means atony throughout all the pelvic viscera, and weakened portal circulation. Woe to our gynæcologists if our ladies should take to the modes of the Bedouin or Tartar women, for their offices would be empty. I have known an old gentleman, who had been spending three years of catheter life, empty his bladder naturally after a month's open-air breathing at Palm Beach, Fla. But last, and by no means least, general muscular weakness means weakness in the whole circuit of the circulation from the heart to the remotest arterial twig and back again, for here muscular function is everywhere the dominant element.

Let fresh air be systematically and continuously provided to enter the lungs without effort on the part of the patient with failing heart, and a great train of serious symptoms will finally vanish, and that not temporarily as too often with drugs. We have also for our encouragement here the physiological fact that no one of the higher tissues has such recuperative powers as muscular tissue, as may be witnessed in the rapid recovery from the remarkable muscular wasting of typhoid fever.

Among drugs, on this account alone, I never fail to administer iron as soon as I can, and keep it up continuously in chronic heart disease, because the one business of iron in our blood is to help us breathe.

There are other drugs, such as mercury, the iodides, and arsenic, which are slow acting and constitutional, and not functional in their effects, whose modes of operation we do not know, but which I feel assured are often of great service in chronic cardiac disease. The bichloride of mercury, given in doses of gr. $\frac{1}{24}$ three times a day for a week, has been for long a favorite remedy with me for chronic endarteritis. It may then be left off for two weeks and afterward resumed as before. Among the iodides the sodium is much to be preferred to the potassium salt, because potassium in any combination is weakening to the heart. I have prescribed it in doses of gr. v. three times a day for weeks and months, and in many cases with such undoubted advantage that I rarely fail to administer it sooner or later in chronic enlargement of the heart, accompanied by arterial disease. Dr. Balfour in his work on the senile heart praises a combination of the liq. arsen. hydrochlor. with the liq. strych. hydrochlor., equal parts, as the only liquid preparation of the two drugs which will make a clear solution. The dose is from four to six drops. I have frequently used it, and in some cases in old people with benefit.

Finally we have the completest contrast to the recommendations for absolute rest in bed and heart sedatives in acute carditis, in Oertel's mountain climbing for heart disease, and in the various forms of resistant muscular exercise, massage, and Schott's saline and carbonic bath courses. These are all excellent in principle and frequently in effects, but they may also be fatal in cases not adapted to them. The salient fact demonstrated by these measures, each in its separate way, is that muscles ought to be made to breathe as well as to contract, and that unused muscles fail in nutrition because disuse lowers their consumption of oxygen. The muscles use up more oxygen than all the other tissues put together, and when by massage and by passive exercise, and lastly by graduated resistant exercises, every accessible muscle is made to call for more arterial blood, the whole muscular apparatus, including that of the heart and blood-vessels, shares in a reinvigoration which may long be beneficially felt in an enfeebled heart wall. Meantime the cutaneous stimulation of the carbonic and saline baths reopens vast tracts of closed arterioles and by so much lessens the tired heart's work, for high arterial tension always implies undue cardiac labor. In the appropriate cases the benefit following upon these modern methods is sometimes marvellous, but an irremediably diseased aorta or arteries, permanently rigid throughout the body, cannot safely be subjected to the strain of these measures.

Pneumatocele.—A sonorous tumor formed above the ear in a man, aged forty years, whenever he blew his nose. Under pressure it would disappear with a whistling noise. The patient, who has a discharge from the ear on this side, hears better when the tumor is distended with air. Treatment was by wide incision and osteoplastic closure of the orifice.—BERGER, *La Méd. Mod.*, December 16, 1899.

THE INOCULATION WOUND OF LUES.

By CHARLES WARRENNE ALLEN, M.D.,
NEW YORK,
CONSULTING SURGEON (GENITO-URINARY) TO THE CITY HOSPITAL.

The diagnosis of lues in its earliest stages is as important as it is often difficult. Perhaps too much stress has been laid upon the typical Hunterian chancre and a sore with classically indurated base as necessary features of the initial lesion before a diagnosis can be ventured. It is my intention in this brief communication to speak of some typical lesions upon various portions of the body which have in my experience marked the site of luetic infection. Contrary to the teachings of most writers I have insisted upon the great desirability, if not an absolute necessity, of beginning treatment both local and constitutional at the earliest possible moment, if it is expected to get the best results in this affection. It is also of the utmost importance from the side of prophylaxis that the dangers be early appreciated by the patient, so that necessary precautions may be taken to limit its spread to others in accidental ways. To be sure, a very large proportion of unusual sites for the inoculation wound, and of wounds acting in unusual ways, is found in patients who present themselves with secondary evidences so well marked that the primary manifestation is carefully sought for.

Such was the case in a young man seen by me for the first time several weeks ago. A typical maculopapular eruption occupied the face, trunk, and penis, forming erosive lesions about the moist glans penis and prepuce. Upon the left side of the neck and about the angle of the jaw was a pronounced and very hard swelling made up of a mass of lymph nodes. There had been no preceding lesion upon the virile member nor within the oral cavity. The scalp and post-auricular region on the left side were the seat of a marked seborrhœal eczema of long standing. The appearances about the ear were peculiar and at once attracted attention. The eczematous infiltration was more marked than is usual; the color was duskier, and a few outlying papules were rather coppery in hue. The skin of the whole region behind the ear was firmer to the touch than one would expect from an uncomplicated eczema. The history given was that on November 3d last in an election fight his opponent had bitten through the external ear. A simple dressing had been applied without stitches, and the wound appeared to do well for about three weeks, when it began to do badly, although the description is not that of a typical chancre. A physician was visited, who ordered an ointment.

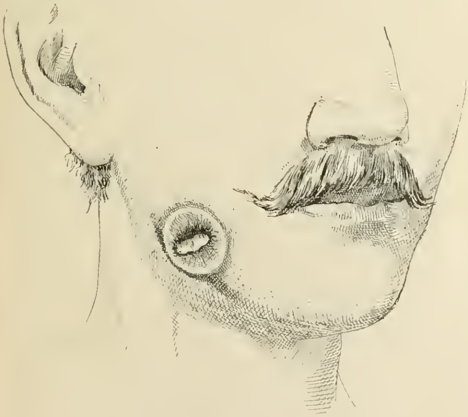

Fig. 1.

When first seen at the clinic, the external ear was deformed—chiefly from the surrounding infiltration; the concha bulged forward and the lumen of the canal was almost occluded. It was chiefly upon the color and induration of the eczematous patch behind the ear, and the enormously enlarged and indurated nodes, that the diagnosis was made. Under inunctions of blue ointment the whole picture has already changed and the seborrhœal eczema as well is rapidly disappearing.

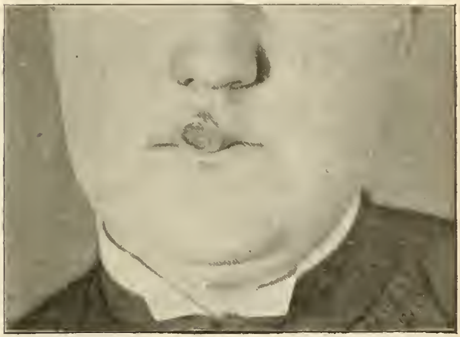

Fig. 2.

In chancres about the face and head, as in the case just related, swelling of the lymph nodes is almost invariably excessive, and is a point to be remembered in differentiation from sycosis, ordinary wounds, cold sores upon the lips, etc.

Infection due to bites is not unknown in literature, and many extra-genital chancres undoubtedly have this origin, in which no definite history of such injury is acknowledged by the subject. I have in my notes of cases three or four in which injury with the teeth was acknowledged, and I have seen others in which I strongly suspected it. Fist blows are sometimes as dangerous as injury by the teeth. On November 22, 1886, M. P—— came to me with a chancre upon the bridge of the nose which had followed an injury inflicted in this way by her husband two months before. She had been to a "black-eye artist" and had the ecchymotic area painted. The possibility of an infection at the hands of the artist, perhaps through moistening the brush in his mouth, could never be excluded.

Slight injuries are not infrequently the starting-point of infecting sores, and it is oftentimes an impossibility to discover whether the object inflicting the wound has been itself infected, or whether the solution of continuity has afforded the opportunity for subsequent entrance of virus derived from an entirely different source.

A gentleman came to me some years ago for an opinion as to the nature of a round ulcerating sore hidden by the mustache (Fig. 1). He stated that in curling the ends of the mustache the barber had burned the lip some weeks before. There was not much induration at the base, and, while stating my strong suspicions, I advised temporizing. Confirmatory signs soon appeared. Here the possibility of an infecting kiss after the injury has to be considered. I have many times seen chancre of the lip which followed upon a very clear history of fever sore, but there was likewise often a clear history of suspicious kissing before the herpes had healed.

While I believe it to be among the great rarities of practice that acquired lues should exist without an initial lesion, I have seen the primary wound so insignificant from start to finish, and the signs of induration in an infecting ulcer so slight, that I can readily believe that the point of inoculation often has so little to show for itself that it escapes detection. Twice recently I have observed upon the finger in physicians papular indurations, which, though they marked the point of entrance of the poison, never reached more than a pea-size development. Then, too, in women we must remember that by the time the wound is looked for upon the cervix or vagina it has perhaps healed.

Acquired lues without chancre may exist if we are to understand by the term chancre an induration even approximating that of typical lesions. As to the location of accidentally acquired infecting wounds and their relative frequency, I shall speak now simply from my own experience, and I must premise with the statement that I have recently been impressed with the relatively large number of accidental infections which have fallen under my eye. In one hundred consecutive histories of lues of all stages and varieties taken from my private record book, a lesion upon which a diagnosis could be made was either present, or there was a clear history and scar evidence of extra-genital infection, in fifteen instances. The lip was involved eight times, the finger four times, the hand once, the nasal septum once, and the cheek once. In twenty-eight subsequent histories there were ten instances of primary lesion occurring upon what are generally considered unusual situations. In this series the lip was implicated twice, the cheek twice, the finger three times, the nipple once, the eyelid once (Fig. 3), and the arm once.

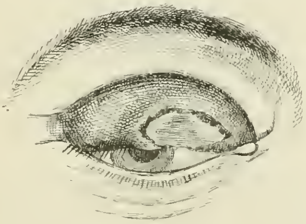

Fig. 3.

Believing these figures to show a much larger percentage of accidental infection than holds true when large series of cases are studied, I have turned to public practice for a comparison. In a series of two hundred consecutive cases of lues at the Good Samaritan Dispensary I find twenty records of extra-genital chancre being present, or good evidence was shown of such having been present. The lip was the site of lesions seen by me personally in eight instances. In one case there was a double chancre involving both lips resulting from a bite. In two instances a man and wife came together for treatment, both showing typical indurations. Once the husband's sore was on the right lower lip, while that of his wife was upon the left upper one (Fig. 2). This case is almost identical with one I published in 1885 in the March number of the *Journal of Cutaneous and Venereal Diseases*. At the time I did not know that there was any connection between the two patients, but after publishing the paper I learned that the woman who had left her husband and burned her lip with creosote had become most intimate with my young male patient. Their lip lesions were here also rights and lefts. The dangers to other members of a family arising from lip lesions, whether primary or secondary, has become pretty generally known, but is seldom brought home more forcibly than in two succeeding cases in this list: a young woman, A. H——, was treated for a chancre of the lip, and despite instructions as to precautions necessary the next extra-genital chancre seen was one of the tonsil in her sister.

Next to the lip comes the cheek with four instances to its credit, the nipple with two, and one each for the nose, ear, chin, tonsil, rectum, and back.

Statistics must vary of necessity according to the line of practice in which the lesions are seen. The gynæcologist undoubtedly finds a large proportion located on or about the cervix, while those observed by the laryngologist would make tonsillar lesions seem more frequent.

Reviewing then this series of cases we find in less than four hundred consecutive records of lues there were no less than forty-six non-genital inoculations. This is probably a larger proportion than will be found reported elsewhere, and, like all statistical data, is subject to error. I simply give the records for what they are worth, not as proving anything, but rather once more and in another way to direct attention to an unfortunate prevalence of non-licentious lues.

126 East Sixtieth Street.

CHORION EPITHELIUM AND DECIDUA IN TUBAL GESTATION.[1]

By B. S. TALMEY, M.D.,
NEW YORK.

Physiologists are not as yet agreed on the question regarding the origin of the chorionic epithelium, although many observers have for years attempted its definitive solution. Even the number of layers of the villous epithelium is as yet a matter of controversy. While most of the writers describe a double epithelial layer, there are yet some opposing this opinion. Moreover, the believers in a double layer attribute the different layers to a different origin.

Turner found two layers in the epithelium of the chorion, and considers the lower layer as the proper chorionic epithelium, which atrophies at the end of pregnancy; the upper, more persistent layer being of maternal origin. He found that in the whole series of placentæ there is interposed between the vascular chorion of the fœtus and the maternal blood-vessels a layer of cells, which is in close relation to the maternal blood-vessels. They constitute, or are derived from, the epithelium of the uterine mucous membrane and belong to the maternal part of the placenta. Kameneff considers the lower layer as the proper chorionic epithelium, but believes it to be persistent, and contrary to Turner he found the upper layer only at some points of the villi, and only in immature placentæ. Langhans considers the upper layer as the only proper epithelium, the lower being a formation of the connective tissue of the membrana granulosa. Kastschenko finds the epithelium of the chorion in the human placenta to consist of two layers: the upper, "protoplasmatic," forms the main mass surrounding the chorion and villi like a continuous multinuclear plasmodium, the lower being derived from a proliferation of the single cells of the upper layer. Both layers are accordingly of fœtal origin. Kupffer also finds a double epithelial investment of the chorion, but he does not believe that the villi stand in any relation to the uterine glands. Minot believes also in the existence of two layers. In regard to their origin, he agrees with Kastschenko that the external covering is fœtal ectoderm. Hofmeier, on the other hand, claims never to have found a double epithelial covering in specimens of placentæ of later months, and declares the contrary findings of others to be an optical delusion. Keibel found a double epithelial lining of the villi, but he could not see the pretended intrusion of the villi into the crypts of the uterine glands. Klein found a double epithelial covering of the villi even in the tubal placentæ. They are intimately surrounded by the decidua; otherwise there is little difference between the uterine and the tubal decidua. According to Seleuka, the villi of the chorion invade the uterine glands, and in advancing further receive the flattened glandular epithelium as a second layer for their investment.

---

[1] From Professor Ribbert's pathological laboratory, University of Zürich, Switzerland.

Thus most of the authors describe a double layer of the epithelium of the chorionic villi, and many of them believe one layer to be a derivative of the maternal uterine glands. The disputed question could, therefore, be answered by a comparison with the placenta in tubal gestation, where the villi are embedded in a glandless mucosa. Inasmuch as few authors only have been fortunate enough to examine a tubal placenta *in situ*, and especially a full-grown placenta as in the following case, I thought this case not an unsuitable one to contribute somewhat to the solution of the question at issue.

In January, 1899, Professor Ribbert, the director of the Pathological Institute of the University of Zürich, received a woman's internal genital tract, obtained by laparotomy. The operation was performed for a full-time tubal gestation. A living child was removed. The macroscopical inspection of the preparation, hardened in alcohol, shows the uterus and right adnexa to be quite normal. The left Fallopian tube, 4 cm. away from the uterine opening, is dilated into a sac, the length of which is 20 cm., the circumference 35 cm. The placental site covers almost the entire posterior wall of the sac. The diameter of the placenta is 12 cm., the greatest thickness 5 cm., and the rest of the placenta, as yet adherent to the tubal wall, 1–2 cm. The thickness of the anterior wall of the sac is 2 mm. Nearing the placental site the wall of the sac becomes gradually thicker, ending in an elevation around a pit in which the placenta is situated. The thickness of this edge is 7 mm. The wall of the tube arching over the placenta is greatly thinned out, being at some points less than 0.5 mm. in thickness. The tubal canal leading from the uterine cavity into the sac does not admit a probe. Of the left ovary nothing is distinguishable.

Five months later Professor Ribbert delivered to me this specimen for microscopical examination. I took out small pieces from several points and cut them partly in paraffin, partly in celloidin. The structure of the anterior wall consists mostly of connective-tissue fibres of the usual type. Of the muscular coat only isolated fibres are seen scattered between the connective-tissue fibres. Nowhere could I find a continuous muscular coat. There is cellular infiltration of lymphocytes as well as leucocytes through the whole tissue. Fibres of red blood cells are lying in spaces between the connective-tissue fibres. These spaces have no endothelial lining. The blood-vessels, especially the veins, appear to be enlarged. All traces of the tubal mucosa have disappeared. The entire external surface of the tube is covered with an exudate consisting of fibrinous material, and fibrinous-looking connective-tissue strands hang down from the wall.

At the placental site the wall of the tube is greatly thinned, consisting at some points of the thickened serosa only, which is surrounded by a thick layer of fibrin. The serosa consists of a layer of thick connective-tissue fibres. Here and there separated muscular fibres can be seen. The next layer toward the inner surface of the sac consists of more loose connective tissue containing less lymphocytes and red blood cells. In this part isolated villi scattered between delicate connective-tissue fibres can already be noticed. Gradually the connective tissue disappears, and the villi are seen in all directions close to each other and separated only by fibrinous material, leucocytes, and islets of red blood cells.

In the placenta proper the villi graft themselves on a fibrinous layer, which does not contain any cellular elements. The nuclei have almost entirely disappeared. There is no recognizable intervillous sinus system. The villi consist of a homogeneous-looking fibrinous connective tissue. In some villi degenerated nuclei or granules are embedded. The stroma of the villus, staining a bright pink by hæmalaun and Van Gieson, is surrounded by a ring of fibrinous material of dark yellow color, which is distinctly differentiated from the surrounding tissue. But even in this margin, which I hold to represent the degenerated ectoderm of the villus, cells and nuclei have entirely disappeared. Nearer the tubal wall the villi impinge upon a fibrinous stroma of an alveolar structure, which contains numbers of cells which are in no way different from the common lymphocytes. Sometimes they resemble rather the inflammatory elements in salpingitis. At some points the nuclei have a narrow margin of protoplasm and resemble the cellular elements of dysmenorrhœa membranacea. These enlarged connective-tissue cells, which sometimes take an ovoid form, could, superficially seen, be mistaken for decidual cells. But on examining the preparations more closely we see that they present different characters from the real large vesicular decidual cells. They are different in form as well as in size, and the typical stratification of the true decidual cells is also missing here. The fibrinous intervillous stroma has at some points a close resemblance to young granulation tissue. At times it resembles a fibrinous exudate, like that in diphtheritic membranes. The cellular elements of the villi have disappeared even in this richly cellular tissue. In the stratum next the sac's cavity, the nuclei of the intervillous substance are becoming more sparse, and later on in the placenta proper disappear entirely. Where normally the intervillous spaces are found, slits filled with a partly homogeneous, bluish-red, partly filamentous, scarcely staining mass are seen, through which small, round degenerated cells without nuclei, of the size of soaked red blood corpuscles, are scattered. At the advanced stage of this pregnancy it is entirely out of question that this mass could represent, as Gussener thinks of his case, a kind of uterine milk for the nutrition of the embryo.

The structural modifications in our case afford us four points of interest:

1. The hyperplasia of the Fallopian tube in tubal gestation consists only of a proliferation of the connective tissue and not of the hypertrophic muscular coat. The muscular part, on the contrary, has almost entirely disappeared by the direct destructive action of the growing connective tissue.

2. The tube, at the placental site, is thinner than normal, consisting only of thickened serosa and a layer of fibrin without any muscular elements. The growing placenta had the same effect upon the tube as a malignant growth.

3. Decidual cells are entirely absent in this full-time tubal gestation.

4. The stroma of the chorionic villi, as well as their covering, have entirely lost their cellular elements.

These histological modifications, I am inclined to think, may serve to contribute to the solution of the question about the origin of the chorionic epithelium, and how far the maternal tissue contributes to the formation of the placenta by furnishing decidual tissue. Is the development of the fœtal part of the placenta in the Fallopian tube the same as in the uterus?

But before analyzing this question at length, I wish to cast a rapid glance at the strange atrophy of the tubal muscular coat in our case. In spite of the immense thickness of the posterior wall of the sac, the muscular coat has almost entirely disappeared. At the placental site especially no circular fibres could be found, and through the entire wall of the sac I failed to see a continuous muscular layer. These findings are at variance with the accounts given by other observers, who found hypertrophy of the muscularis. Although Aschoff, who in a case of tubal gestation of two to three weeks' duration found also an atrophy of the tubal muscularis, remarks that most of the reported cases of hypertrophy of the muscular elements in tubal gestation have not been microscopically examined, yet even if the recorded hypertrophy really belonged to the muscular layers and was not mistaken for the proliferated connective tissue our observation could easily be explained. The described histologically examined cases of tubal pregnancies concerned young ova between three and twenty weeks. I searched in vain through the whole current literature to find a microscopically examined case of a full-time tubal pregnancy. My interpretation would, therefore, be that at the outset, when the whole tubal wall begins to hypertrophy, the muscular coat is also participating in this hypertrophy, but later on the proliferation of the connective tissue predominates. This proliferation bursts first the muscular fascicles and later on destroys them entirely. Fueth, it is true, already found in a very young ovum a cuneiform bundle of villi pushing forward and in close attachment to the tubal wall, and surrounded by cells similar to the elements of the cell-columns derived from the tips of the villi. The bundle was invading the muscular fascicles and dislodging them. The ovum was splitting the tubal muscularis, lifting off the submucous layer, and in its advance destroying almost entirely the circular layer. Fueth also mentions a preparation from the women's hospital of the University of Kiel, in which the ovum was lodged very near the open end of the fimbriæ. He emphasizes the extraordinary shrinking of the tube at the site of the ovum, contrasting with the greatly thickened neighboring wall. At the site of the ovum the wall was scarcely 1 mm. thick, and consisted only of peritoneum and delicate connective-tissue fibres. Muret, in whose case the ovum was also inserted at the open ostium abdominale, noticed the wall at that point to be greatly thinned; mucosa and muscularis had entirely disappeared, and the wall consisted only of peritoneum. Prochownik describes, in an ovum situated near the ampulla, intact chorionic villi with fresh budding closely beneath the serosa. Excepting the serosa and a very thin layer of connective tissue nothing of the tubal wall was left. Leopold found in a case of tubal gestation of eight weeks' duration, in which the ovum was inserted at the abdominal end, the muscular coat greatly diminished and at some points distorted and displaced. Thus even in very young ova a loss of the tubal muscular tissue was observed.

Now a few words will suffice about the strange phenomenon of the chorionic villi having entirely lost their cellular elements. According to Turner, the lower layer, which he considers the only chorionic epithelium, atrophies at the end of pregnancy, while Kameneff considers the lower layer to be persistent, and finds, on the contrary, the upper layer covering only some points of the villi, and even this only in immature placentæ. Eckard noticed at the cell layer of the villous epithelium a different development at different times of the formation of the placenta. Very early, certainly from the twelfth week, the cells cannot be found everywhere. According to Langhans, there is only at the tips of the villi a fast and durable attachment between the cell layer and the maternal tissue; at the other parts of the villus this layer becomes thinner and cannot be seen in the last three months of pregnancy. Thus the opinion of most of the authors is that one of the two layers of the villous epithelium, even in uterine full-grown placentæ, is doomed to atrophy. We could, therefore, assign the entire loss of both layers in our case of tubal gestation to the unfavorable conditions under which the placenta reached its full development.

But the question immediately presents itself, why the nuclei in the stroma of the villi disappeared. In about twenty full-time uterine placentæ which I have examined for comparison's sake, I always found deeply stained nuclei in the villous stroma as well as in the ectoderm. I would not try to give a definite answer to this question. But the histological modifications of the villous covering would allow the following interpretation:

The cell—Dr. Langhans' layer—is, according to the opinion of the discoverer himself, finally bound to atrophy, and the villous covering consists then of the "protoplasmic" layer or syncytium only. The syncytium is declared, as above alluded to, by many observers to take its origin from the flattened and changed epithelium of the uterine glands. The mucosa of the Fallopian tube, not containing any glands, could not, therefore, furnish to the villi of the tubal placenta any cell material for its syncytium. The villous covering accordingly consisted from the very start of one layer of Langhans' cell layer only. When this layer atrophies later on, the villi are entirely denuded of their epithelial covering. The accounts given by those who describe a double epithelial covering in early stages of tubal gestation are surely difficult to reconcile with my interpretation. But I have no doubt in assigning a purely optical delusion to such findings, as Hofmeier does to the assertion about the later stages of uterine pregnancy.

The entire disappearance of decidual structure in our case is in conformity with the observations of Virchow, who claims the absence of a decidua in tubal gestation. Lately Aschoff came to the conclusion, from the cases he examined, that a real decidual development does not take place in tubal gestation, not even at the placental site. Otherwise he finds no difference between the structure of the uterine and that of tubal placentæ. The cell proliferations of the fœtal epithelium at the tips of the villi lead to the development of columns of cells, which in coalescing form a large sucking-plate. This plate invades the tubal wall, destroys mercilessly mucosa and muscularis, and opens the blood-vessels for the placental blood circulation. Prochownik also emphasizes the slight development of the decidua tubaria. Kossmann speaks also of a spotty appearance only of decidua around the blood-vessels in tubal gestation. Berry Hart says that in extra-uterine placentæ we begin to see the serious damage caused to the placental structure by its development in connective tissue. The villi are less perfect in contour, blood extravasation is present, blood crystals are in abundance, while the decidual cells are few and less perfect. We may say, he continues, that the development of the extra-uterine placenta is a destructive one, reducing the placenta practically to compressed villi, while the serotina is destroyed and replaced by blood crystals and organizing blood clot. Gülland found that the decidual cells become more and more degenerated and are replaced ultimately by a fibrinous layer, which contains immense numbers of leucocytes, most of which are also degenerated.

Contrary to these authors, others have seen a perfectly developed decidua. Orthmann found in eight of his ten cases of tubal pregnancies all stages of the changes of the mucosa to decidua. Zedal finds certain cells in the tubal serotina having the same shape and quality as the well-known decidual cells in the uterine mucosa. Yet he mostly observed a considerable proliferation of the intercellular substance. The outline of the cells is often more or less blurred, and finally the nuclei of the cells are destroyed in the more changed parts. In place of decidual tissue a homogeneous-looking fibrinous mass could be seen, which at some points has a striated appearance. He attributes the degeneration of the decidua to mechanical causes. In our case a full-time child was removed, and the pressure in the tube was consequently immense. The disappearance of the decidua could, therefore, be attributed to mechanical causes. Walther finds a delicate connective-tissue stratum bordering the epithelium, in which large connective-tissue cells are to be seen in large aggregates. These piles of cells can be traced even within the intermuscular connective tissue, and here again near the perivascular tissue. Thus the tubal wall is, in fact, filled with nests of decidual cells as if invaded by the cells of a malignant growth. In our case the tubal wall is also filled with nests of cells, but they resemble in no way true decidual cells. Webster, Goebel, and Mandel found a partly developed decidua even in the other non-pregnant tube. In our case no traces are found even at the placental site. This phenomenon cannot be easily interpreted, but I incline to accept Aschoff's view and that of the other writers, that in our case also a development of a decidua never existed.

The fact that our fœtus reached its full development would surely suggest the idea that this tube furnished to the embryo a better lodgment by the development of a true decidua. But, on the other hand, we find the villi advanced to the tubal serosa. This phenomenon refutes the last assumption; for if the proliferating fœtal cell-masses had found in the decidua a cushion, rich with blood-vessels, to furnish enough blood to the intervillous spaces for the nourishment of the embryo, the villi would not have penetrated so far in search of a highly vascularized tissue. They never do this in uterine pregnancies except in deciduoma malignum. The fact that the villi advanced here through the mucosa and muscularis to reach the well-vascularized serosa makes the view acceptable that no decidua was ever developed here.

As to the possibility of the fœtus reaching its full-timed development, although the wall is gradually becoming thinner as the size of the fœtus increases, there cannot be any other interpretation than that the menacing rupture of the tube by the contractions of the hypertrophied muscular fibres in the early months of the pregnancy was prevented by the immense proliferation of the peritoneum over the thinned part. In the later months, when the muscles have already atrophied, considerable contractions cease to occur, and the danger of a rupture or a tubal abortion is greatly diminished.

I would not try to give a definite answer to the question why a decidual development had not occurred here. According to Strahl, the uterine epithelium changes into a syncytium, or simple protoplasmatic mass with deeply staining nuclei. This layer is located between the stroma of the uterus and the connective-tissue groundwork of the chorion and villi. It would, therefore, seem that in the tube the mucosa has a different destination. Here, as Frommel, Wyder, and Abel claim, the mucosa is doomed to atrophic changes by the great pressure within the amniotic sac. On the other hand, if the decidual cells originate, as Hennig and Abel claim, from the leucocytes, immigrated from the blood, or, as Aschoff thinks, that the decidua takes its origin from the proliferated fœtal epithelium at the tips of the villi, it is hard to explain why a decidua should not develop in tubal gestation as well. Langhans, Orthmann, and Dobbet claim that the origin of the decidual cells is from the spindle-shaped cells of the uterine mucosa. Now the tubal mucosa, having normally only one function, namely, to forward the ovum into the uterus, would not have the faculty of furnishing a decidual proliferation even under changed conditions. But if the decidua was a product of the villous epithelium, nothing would prevent its development in extra-uterine pregnancies as well.

Anyhow, the main difficulty of embryonic histological researches is and remains yet, as Marchand appropriately remarks, our defective knowledge of the genetic meaning of the epithelial covering of the chorionic villi.

SOME REMARKS ON WHOOPING-COUGH AS SEEN IN DISPENSARY PRACTICE.

By WALTER A. DUNCKEL, M.D.,

ATTENDING PHYSICIAN TO DISEASES OF CHILDREN, NEW YORK DISPENSARY; INSTRUCTOR IN DISEASES OF CHILDREN IN THE SUMMER SCHOOL OF CORNELL UNIVERSITY MEDICAL COLLEGE.

THE cases forming a basis for these remarks were taken from my service at the New York Dispensary between November, 1894, and February, 1900. Except those whose parents speak only Italian, all children up to the age of fifteen years are referred to on the occasion of their first visit to this class.

Two hundred and sixty-one cases of whooping-cough are recorded among 22,666 new cases of all diseases. This probably does not accurately represent the relative frequency of the disease, as the diagnosis was entered in the books only when the history was definite or a paroxysm occurred during examination.

Aside from these there were other cases in apparently incipient stages that had not declared themselves. It is almost needless to state that a paper of this sort is necessarily lacking in scope. Many of the patients did not return after a diagnosis was made, for a dispensary clientèle possesses unbounded faith that the disease will hold its course regardless of an array of drugs. A mild case is not likely to return unless some complication arises, making the child worse. Although provision is made for visiting all patients with severe illness at their residences, some of these passed from observation. An accurate estimate of the duration of the disease, efficacy of treatment, and mortality cannot therefore be obtained. It is with these limitations in view that the paper is presented. Thus recorded, the relative frequency of whooping-cough to that of other diseases is a fraction over one per cent. The percentages by years are as follows:

Twenty-nine per cent. during 1895; twenty per cent. during 1896; thirteen per cent. during 1897; fifteen per cent. during 1898; sixteen per cent. during 1899. For the three months of November and December, 1894, and January, 1900, there were seven per cent. of the cases. Fifty-five per cent. were seen in the summer months and during September and January.

In point of frequency of sex sixty per cent. were females and forty per cent. males. Sixty-seven per cent. of cases occurred between the ages of six months and five years. The percentages fell to one per cent. for the eighth, and the same for the ninth year. There were but two cases at three months and none later than ten years. As the age was entered at the first visit there is a slight source of error equivalent to the length of time the disease had existed before advice was sought. In about one-half of the cases in which notes were made of the duration of the disease before coming for treatment, the characteristic cough had been observed from two to three weeks and was then very pronounced. The eighth and twelfth weeks furnished the next largest number of patients—periods when severe complications or relapses are rife.

Complications.—The number of cases in which complications were noted at the time of the first visit or subsequently is sixty-seven—or 25.6 per cent. Sixty-one per cent. were females, showing no increased liability of sex. In speaking of complications it may be well to state that bronchitis has been included in this category. While the lesion is so common as to be a part of the disease in nearly every instance, there were many cases without physical signs. Only those are included in which signs were present. The complications naturally arrange themselves in two groups: (*a*) Those dependent upon the violence and strain of the paroxysm; (*b*) those due to lesions associated with the disease.

Of the first group there were: Hemoptyses, 6; epistaxis, 2; subconjunctival hemorrhage of both eyes, 1; umbilical hernia, 2; ulcer beneath the tongue, 2.

Of the second group there were: Mild bronchitis, 2; bronchitis of moderate severity, 25; severe general bronchitis with involvement of the small bronchi, 8; broncho-pneumonia, 19; tuberculous meningitis, 1; adenitis of the anterior cervical glands, 1; pericarditis (plastic stage), 1; malnutrition and wasting, 8. Four of these cases terminated fatally—three with broncho-pneumonia and one with meningitis. As some had more than one complication, the total number of cases under this heading does not equal the number of complications. Aside from the sixty-seven cases presenting complications, measles coexisted in two and scarlatina in one. Forty-six per cent. of the complications occurred during the months of January, July, and August; 13.5 per cent. in January; 13.5 per cent. in July; 19.5 per cent. in August. As only thirty-two per cent. of the whole number of cases were seen during these months, and the complications exceed them by so much as fourteen per cent., it seems fair to assume, even from so small a number of cases, an increased liability to complicating disorders during these months. Gastritis did not occur as a complication, although vomiting with the paroxysms was a frequent manifestation. Gastro-intestinal disturbance existed in the wasted babies, but was not directly assignable to the infectious disease. Diarrhœa in those not artificially fed or suffering from malnutrition did not add a serious phase to the malady. It was observed almost entirely during the hot season. Wasting is used merely as a descriptive term and does not refer to essential infantile atrophy. There were eight of these cases—three of them under one year, two between one and two years, and three at three, four, and five years. Two of those under two years were artificially fed, and one was insufficiently nourished at the breast. The two at three and four years had broncho-pneumonia, and the one at five developed tuberculous meningitis. In looking over the statistics to inquire if possible into the relation shown between the frequency of the disease at stated ages and the occurrence of complications, there seems to be an increased liability to those of the graver sort in the very young, but no increased liability to complications in general. Thus fifty-eight per cent. of all the cases of whooping-cough were observed between the ages of six months and four years, while fifty-nine per cent. of the complications—fourteen being cases of broncho-pneumonia—occurred during the same period. There is a falling off between the third and fourth years as shown by sixteen per cent. of the cases having only six per cent. of the complications. Between the fourth and fifth years the ratio is increased to fifteen per cent. of the complications for ten per cent. of the cases. Only one patient had convulsions, and these were due to the onset of a broncho-pneumonia. Cerebral hemorrhage can be excluded, as the patient was under observation for nearly three months. Broncho-pneumonia was a late complication, occurring as a rule about the eighth week, although one case was seen in the third week.

Relapses of whooping-cough were noted in five cases (possibly recrudescences would be a better term). These came for treatment after having gone through the period of characteristic cough, followed by a short period of immunity from it, and this in turn succeeded by a revival of the whooping. Four of the cases had persisted three months and one for two months.

The two cases of ulcer at the junction of the frænum of the tongue with the mucous membrane on the floor of the mouth were observed after the disease had existed for three months in one and seven weeks in the other. One child was fourteen months and the other two years old, and as they were seen for the first time there was no saying when the ulcer first appeared. The ulcers were about one-sixteenth of an inch in diameter, superficial, grayish, not associated with stomatitis, and not painful.

Loss of control of the sphincter ani during the paroxysm was not a troublesome affection except in one child three years old.

The average duration of the disease cannot be given with any exactness owing to insufficient data. The longest case recorded was four and one-half months and the shortest two weeks, the latter including the paroxysmal stages only.

Before concluding, a few facts may be gathered from three interesting cases accidentally left out of the foregoing enumeration.

The first was that of a boy, eighteen months, breast-fed, who came for the first time with an empyema of the left pleural sac. Operation was done by incision and gauze drainage, as the child was too weak for more elaborate surgical measures. The paroxysmal cough was frequent and severe, but seemed to favor expansion of the lung. Recovery was rapid and complete. Three years later he was strong and healthy, and but for the scar there were no physical signs. The second was a girl, breast-fed, extremely wasted and having diarrhœa. The whooping persisted four months, and in the later stages the chest was never free from fine moist râles. Tuberculous involvement seemed highly probable, but recovery was complete. Two years later the child was well nourished, and a physical examination gave a hyper-resonant note over a chest that was deep and emphysematous in type. There were no changes in the breath sounds, and the heart was normal. The third case was that of a boy who acquired whooping-cough at twenty months, which ran its course in eighteen weeks. He was in good flesh two years later, the chest emphysematous in shape, the resonance somewhat high pitched, and the breath sounds were normal. There was no abnormal cardiac condition.

It is only surprising that emphysematous changes are not more common. Tuberculosis would seem to have an inviting field for operation in whooping-cough. It is difficult to understand why it should not be of more frequent occurrence. When it makes its appearance it is far more likely to be late than early. Without wishing to advance on untenable ground, it may be that the organism is somewhat protected against a secure lodgment of the bacilli by the very violence and frequency of the cough. This is, to a certain degree, borne out by the occurrence of broncho-pneumonia after the spasmodic feature has become less prominent. The fatality of these pulmonary complications, even as shown in these inadequate records, is suggestive of their tuberculous causation. The one case of tuberculous meningitis occurred in the ninth week, and was fatal in five days. That prognosis, when consolidation appears, must not be invariably bad was clearly shown in one case—that of a girl of three years with well-marked emaciation, and broncho-pneumonia late in the disease, who recovered. Two years later she was well nourished and the physical signs were normal. Evidence that pulmonary tuberculosis is not a common complication or sequela of whooping-cough is also forthcoming from the fact that very few cases of the disease are seen in the service. It is of interest as well that in but one of the cases of meningitis was whooping-cough a factor. Only one case of adenitis was observed, and this was not sufficiently characteristic to be considered tuberculous. There were no cases with bone or joint lesions.

Atelectasis was never regarded as a positive condition. There were cases in which slight dulness and changes in the breath sounds over small areas were suggestive of this condition. If these signs were transient some degree of assurance was felt in considering them to have been due to collapse or defective aeration.

A word or two here in a negative way at least as to the relation between cardiac disease and whooping-cough. The great strain of the paroxysm might properly be regarded as an etiological factor. Not one of these cases, while under observation, had an endocardial complication, nor was it possible to be satisfied that there was cardiac enlargement. Moreover, there have been no cases of cardiac disease on my records in which the etiology was clearly related to whooping-cough. The one case in which there was a pericardial friction sound passed from observation.

It is obvious that careful records of urinary analyses could not be made, and the presence of albuminuria or nephritis as a complication definitely noted. In so far as the external evidence of nephritis is concerned, there was none to indicate any severe forms of this disorder.

Speaking of treatment, belladonna, when indicated by the severity of the paroxysms, was preferred above other drugs on account of safety, tolerance, and expediency. Given in increasing doses it occasionally ameliorated the severity of the seizures. In addition to this a supporting treatment of cod-liver oil and malt preparations was prescribed. That the mothers had faith in the latter was shown by the regularity of their return for the "thick medicine." They cared little for other medication. Antipyrin was prescribed for several cases, in doses of gr. ii. combined with potassium bromide gr. iv., but was discontinued, as these moderate doses were ineffectual. The drug being a depressant it did not seem safe to prescribe it in large doses unless the patient could be kept under the most careful supervision. While there are instances when the disease is exceptionally severe, and vigorous measures may be demanded, it does not seem good therapy in the cases of average severity to attempt to substitute a drug danger for the danger lurking in the disease, unless the former can be proved the less harmful measure. Bromoform has not been prescribed during my service. My predecessor, Dr. John H. Huddleston, made use of it in several cases, and to him I am indebted for the following: "In some an improvement in the severity of the paroxysms without any change in their frequency was reported. Too much reliance could not be placed in these statements, and whatever improvement there might have been did not compensate for the danger of unequal dosage when given in a mixture. On this account its use was discontinued."

If anything is to be learned as to prognosis it should be borne in mind that as a rule the hygienic surroundings in which these children were reared were as poor as can be found in the city. Even so the outlook was not a grave one unless broncho-pneumonia set in. The latter is a complication that can be very largely avoided where better conditions prevail. Such crude methods of treatment as could be adopted afford a great deal of encouragement for the successful management of cases when every detail of diet and hygiene can be carried out in a suitable climate.

SIX NEPHRECTOMIES.

By F. V. CANTWELL, M.D.,

EL PASO, TEX,

LATE SURGEON TO ST. FRANCIS' HOSPITAL, TRENTON, N. J.

THE group of symptoms which accompanied each of the following cases was sufficient for me to make out the condition found at the operation. In my limited experience careful clinical study and frequent examinations are sufficient to clear up the diagnosis in surgical disease of the kidney, in the majority of cases, without the use of instruments to explore the ureter or pelvis of the kidney. I believe that in the hands of men unaccustomed to their use, the latter will do more harm than a clean incision down to the kidney for the purpose of ascertaining its condition. If a disease of the kidney exists which demands surgical intervention and one is not sure of the character of the lesion, he should cut down and see what it is and proceed according to the finding. If one is in doubt as to the presence or condition of the other kidney, he should do as Edebohls advises—look at it. Then one who has experience and common sense will know how to proceed. A man whose sense of touch is at all cultivated can with a finger in the female bladder feel the weak spurt of urine from the mouth of the ureter, and so get some evidence that there is a kidney above.

I have seen but one case in an adult, and that on the post-mortem table, in which but a single kidney existed. This kidney was almost twice the size of a normal one. I have examined the bodies of several new-born or prematurely born babes in which no other cause of death could be found than that one kidney had become entirely cystic from some accident to or defect in the development of the ureter, while the other kidney was normal. I believe that sometimes such cases go on to adult life, and the cystic kidney is entirely absorbed, while the good kidney grows larger in order to keep up with its work. A patient suffers little or no inconvenience from the removal of a kidney that has been disabled for some time, for the reason that the healthy kidney has been in training. As the diseased kidney has slowly fallen off in its capacity for work, the good kidney has taken it up and has been undergoing a compensatory hypertrophy; so that when the grand crisis of nephrectomy comes, the healthy organ takes upon itself the entire burden, and the patient is better off than he was before the operation.

The incision I prefer is one that parallels the last rib; and if the wound thus made binds the hand or interferes with free manipulation, it should be enlarged in whatever direction the surgeon sees fit.

My cases have been as follows:

Case I.—Man, aged thirty-five years, in previous good health. While running across the mill-yard he fell into a shallow ditch. He felt something give way, and immediately there was a sense of fulness in the bladder with a desire to urinate. He was taken home, and four hours afterward was examined by Dr. E. H. Rogers, who found great tenderness over the right kidney and a marked fulness over the bladder. The urine was passed frequently and in small quantities, deeply stained with blood. He was kept quiet; ice-bags were applied to the back, and ergot, gallic acid, etc., administered. This was kept up for three weeks. The patient grew steadily worse, and no symptom was relieved. When I saw him the man was in a state of collapse from bleeding. I advised an exploratory incision and nephrectomy if necessary. The incision was made parallel to the spinal muscles and the kidney brought out. No break in the kidney capsule was found, but the organ had a bluish, bruised look, with some distention of its pelvis. As I was confident that this was the source of bleeding, I removed it. In addition to a looped ligature I put a large catch forceps on the stump to insure against bleeding. I would not do this again, as it made the patient very uncomfortable. This man died after twenty-four hours. Upon slitting open the kidney I found a tear in the substance of the organ, from which came the loss of blood. Its pelvis was filled with old grumous-looking clots as well as fresh blood. A post-mortem examination showed the left kidney to be normal. The bladder was over-distended with blood clots, which I would have removed if the man had lived. This man died of a stillicidium of blood from the torn kidney. The bladder no doubt filled with blood at the time of the accident, and the back pressure must have been great enough to stop any large flow, and so allowed the man to die by inches. His symptoms were by no means severe enough at first to suggest even an exploration of the kidney. The absence of any tumor, due to the peculiar character of the injury—a wound of the kidney without any break in the capsule—was evidence against any serious lesion. There was nothing to do but wait during the first week after the accident. The lesson taught by this case is, that when a man after an injury of this kind continues to pass bloody urine for four or five days, and there is other evidence that he is still losing blood, an incision should be made at once and the bleeding controlled.

Case II.—Man, farmer, aged thirty-four years. He was sent to St. Francis' Hospital, Trenton, N. J., by Dr. Van Neste, of Hopewell, N. J. He had for several years suffered from the passing of stones from the kidney, with all the classical symptoms. During the previous six months he had been passing quantities of blood with his urine. This loss had reduced him to a thin, waxen, listless wreck, completely bedridden. He was dying because he was losing more blood than he could make.

Ten weeks before I saw him, a surgeon had opened his bladder above the pubes in a vain search for the source of bleeding, and a fistula still remained. His pain was always referred to the right kidney, and there was a great deal of tenderness in that region. The kidney could not be felt. I advised exploration. An incision alongside the last rib gave easy access to a kidney that externally looked normal. Palpation disclosed a very suspicious lump in the parenchyma of the organ. Under the circumstances I thought removal the best course—this was in 1894. On cutting into this lump, a sac, an inch and a half in diameter, was opened. This was packed with hundreds of stones, each the size of a millet seed. The wound was closed without drainage, and the man made a quick and perfect recovery. He is still well and attending to business. I have sometimes felt a twinge in my surgical conscience for the removal of this kidney, but have come to the conclusion that it was the proper thing to do. I might have cut into the sac and removed the stones, but this would involve danger from several causes: First, the danger of not removing all the stones; they were very small, and a few might easily have been left; second, of not removing the cause of bleeding, which was fast killing the man; third, of leaving a fistula; fourth, of an abscess of the kidney. The man would not have lived for a secondary nephrectomy. Above all, "*Finis coronat opus:*" the man has been well since the operation.

Case III.—Woman, aged twenty-eight years. She had been sick for a year or more, complaining of great pain in the region of the left kidney and below. Her body showed that she was a big-boned and had been a muscular woman. She was then very thin, pale, and bedridden. The urine was loaded with pus. No bacteriological examination was made. A large fluctuating tumor was found in the left flank and back, extending to the iliac crest. A diagnosis of perinephric abscess due to rupture of a kidney abscess was reached and operation was advised. Owing to the fluctuating mass a longitudinal incision was first made. This gave vent to about a quart of thin, ichorous pus. The kidney was bound firmly down by old adhesions, and as the first incision did not allow of ready access a second one was made along the border of the last rib. This made removal of the organ much easier. A great deal of force was used to break up the adhesions, but the kidney was finally brought out. It was found to be tuberculous, enlarged, and nodulated. An incision was made into a nodule, and cheesy pus found. The ureter was isolated and tied off separately, and the kidney removed. The wound and pus sac were irrigated and packed with gauze, and the wound was loosely sutured. For a few days only the urine was blood-stained and contained some pus. This cleared up very quickly. She recovered well from the operation, but a discharging sinus remained. In the course of about two months this discharge grew so copious that it began to tell on the health of the woman. She was again etherized and about three inches of the ureter was excised. The sac and sinus were well scraped, and the wound was packed and left open. After three weeks this had entirely closed and she left the hospital in good health. She is now working hard as a domestic, and does not miss her kidney.

Case IV.—Man, aged twenty-five years; a strong, sturdy Italian. About an hour and a half before he came to St. Francis' Hospital, he had fallen a distance of three feet on to the end of a railroad tie. He struck on his back in the region of the right kidney. He was brought to the hospital in a carriage, but walked upstairs to the ward alone. He was put to bed, and in a few minutes the resident physician noticed that he grew pale, restless, yawning, thirsty, and had a rapid, small pulse, as if a sudden severe hemorrhage had occurred. I happened to be in the hospital at the time, and was called. I found a vague, ill-defined, compressible tumor in the right lumbar region, with great tenderness. His urine was drawn and found to be bloody. A diagnosis of ruptured kidney was made. The man was quickly prepared and sent to the operating-room. An incision along the last rib was made. Before the kidney was reached at least a quart of loose blood clot was turned out. Loose lying in this mass was the lower end of the kidney stripped of its capsule. The remainder of the kidney was brought out as rapidly as possible; it was still attached to its blood-vessels, and bleeding. The pedicle was tied with a looped ligature including everything, and the kidney was removed. The cavity made by removal of the kidney and blood clot was dried and the wound closed, leaving a small piece of gauze for drainage. The kidney looked as if there had been an explosion from the inside, it was so torn. Besides the piece that was completely separated there were two large rents from which blood had been pouring. Embedded in the cortex immediately beneath the capsule was a stone about the size of a small cherry. This man made an uninterrupted recovery, and when I last heard of him was working hard in a grocery store.

Case V.—Child, male, aged two years. He was brought to my office, supposed to be suffering from worms. The child was of normal size and appeared to be well nourished, with no cachexia. A tumor could be felt on the right side, extending from the lower border of the ribs to the anterior superior spinous process of the ilium. It was freely movable and not at all sensitive. The child suffered no pain, and was brought to me because the parents had noticed a slight failing. The urine contained no blood but a quantity of albumin. A diagnosis of sarcoma of the kidney was reached, and nephrectomy advised. The operation was done August 10, 1898. An incision was made one-half inch from the lower border of the last rib, commencing at the lumbar muscles. This incision had to be carried almost to the umbilicus before the tumor could be delivered. Of course the peritoneal cavity had to be entered, and the kidney was found to be as distinctly an intraperitoneal organ as is the ovary. Its pedicle was formed of a mesonephron surrounding ureter, artery, etc. There were a few adhesions, which were easily broken down. There were no glands noticeably involved. The pedicle was secured by a crossed ligature including everything, and the kidney was removed by a few snips of the scissors. There was practically no bleeding. The peritoneum, muscles, and skin were closed in layers. A strip of gauze was left behind the peritoneum for drainage. This was a mistake, as it left a small sinus difficult to heal. The albumin disappeared from the urine, and the child left the hospital in three weeks after an uninterrupted recovery from the operation. The tumor weighed little short of three pounds, and was a sarcoma which had destroyed almost all the kidney. When I left Trenton in December, 1898, the child was well to all external appearances and felt well. I have since heard that in March, 1899, it died either of an abscess caused by the pedicle ligature or of a return of the growth; very likely the latter. In spite of this I would advise removal of sarcoma of the kidney, no matter at what age it occurred.

Case VI.—Man, aged thirty-one years. This man came to me first in 1887. He had suffered pain during urination "since he was born." He had often to stand on his neck and shoulders with his feet and pelvis elevated before he could pass water. I found a large stone in his bladder, which I removed by lateral lithotomy in October, 1887. The stone was ham-shaped. This relief made a new man of him, and for eight years he worked comfortably at his trade of dish-making. He then began to have attacks of heavy pain in the region of the right kidney. These attacks sometimes lasted for days. They would always commence while he was on his back in bed. During these times it was impossible for him to have a stool, owing to the severe lumbar pain it gave him to strain. This pain no doubt was caused by the dense adhesions found during the operation. He often brought me a sand that he passed with stool. This was uric acid. His urine always contained pus, and after an attack of pain he would pass clear pus. The kidney could be felt at times, and there was a small spot of extreme tenderness at its lower border. This condition continued until life once more became unbearable to him. I sent him to St. Francis' Hospital for a week, during which time a careful study of his symptoms was made and a diagnosis of pus kidney reached. A nephrectomy was advised and consented to. An incision was made parallel to the last rib, and, as the occasion demanded, extended down two inches at a right angle from its outer end. The kidney was reached easily, but a great deal of care had to be taken in enucleating it on account of dense adhesions at its lower border. Several of these had to be tied and cut. During these manipulations the intestine could be seen beneath the thin peritoneum. The ureter was isolated; the vessels were tied with a single ligature after being stripped of all superfluous tissue, and the kidney was removed. A quantity of pus oozed up from the cut ureter, but a probe passed through it into the bladder disclosed no obstruction. It was then fastened to the lower angle of the wound with the idea of flushing it out through the bladder and urethra during convalescence. The lumbar muscles, which were cut partly across, were united, and the cavity of the wound was wiped dry. The wound was then loosely closed and a small piece of gauze left in for drainage. The kidney removed was a fan-shaped collection of abscesses emptying into the pelvis, a typical surgical kidney. He recovered well from the operation, but at last account the open mouth of the ureter was still leaking pus. The chances are that a ureterectomy will have to be done before he is well.

This condition occurred after the lateral lithotomy, but not as a consequence of it. I am inclined to believe that a concurrent specific urethritis was the cause of the pyonephrosis. After the bladder stone was removed he gained in health and strength for several years before he had symptoms of any trouble with his kidney. I could never fathom the significance of the intestinal "sand" found in this case. I have seen the same "sand" in a case in which adhesions had formed between the gall bladder and adjacent intestines.

A Case of Cerebro-Spinal Meningitis due to the Coli Bacillus.—Orazio d'Allocco reports a case in which the spinal fluid removed by Quincke's method was found to contain the coli bacillus.—*La Riforma Medica*, February 14, 1900.

The Night Air of New England in the Treatment of Consumption.—C. S. Millet reports on several cases of tuberculosis treated by sleeping in the open air. The patient takes his own temperature at 9 A.M., 1, 4, and 8 P.M. The rule is, rest in bed during the day long enough to keep the temperature below 99.5° F., or better 99°. The patient keeps a record of the hours spent in the house, and must give a good reason for this time. He is to eat all he can at the three ordinary meals, avoiding pastry and confectionery. A cold sponge bath in the morning and another bath at about 90° F. at bed-time are advised. The nose and throat are carefully looked after and any necessary treatment is given. The patient sleeps in the open air, the one caution being to keep warm. During the cooler months some woollen nightgowns and sheets should be used. Almost the only medicines taken are nux vomica and an occasional laxative.—*Maryland Medical Journal*, January, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 Fifth Avenue.

New York, March 17, 1900.

CARE OF THE INSANE.

THE measures taken for the care of the pauper insane in New York State, although far more humane and rational since the enactment of the "State Care Act" of 1889, are nevertheless susceptible of still greater improvement. In accordance with the provisions of the above-mentioned act, the care of the dependent insane devolves upon the State of New York, and in order to simplify arrangements tending to reach this end in the most satisfactory manner possible, the State was divided into eleven districts, in each of which was placed a State hospital for the reception of patients. The object of this plan is both obvious and excellent, viz., that the inmates may be easily kept in touch with their friends, who are naturally desirous to receive from time to time information as to their condition. With the exception of a somewhat serious drawback this arrangement is said to work admirably. No fault can be found with the care and treatment of the patients when located in the hospitals.

The weak spot in the system is pointed out in the *Albany Medical Annals* for December, 1899, which describes the situation thus: "No statutory requirement exists as to the management of the patient during the process of commitment, and pending transfer to the hospital. In some counties, notably New York, Kings, and Erie, the local authorities have provided so-called 'detention' or 'reception' buildings or wards in connection with existing general hospitals, where the patient's claims as an invalid receive full consideration. Throughout the rest of the State the insane patient is cared for by friends as best they can, or placed in a jail or some convenient receptacle. The hardship of this is at once apparent, and in the more active cases where exhaustion is rapid, consignment to a jail or other 'lock-up' results not only to the detriment of the patient's recovery, but even of his life."

All this is very true, and attention is further drawn to the fact that in those general hospitals in which such reception wards have been established the results have been highly instructive. This has been especially the case at Bellevue Hospital in New York City, where in many instances patients have received so much benefit that they have been discharged as practically cured. The authorities of Albany Hospital, fully recognizing the desirability of introducing reception wards for the insane in general hospitals throughout the State, resolved if possible to cause to be erected a pavilion for the insane in connection with their own institution. The matter was placed before the board of supervisors of Albany County, and in the February number of the *Annals* the announcement was made that the board had declared its willingness to meet the wishes of the projectors of the movement. An appropriation of $18,000 has been set aside for the erection of the pavilion, and plans are now under consideration.

There are undoubtedly many mild cases of insanity for which the treatment provided in the State institutions is unnecessary. A clearer discrimination is needed between acute and chronic cases. If reception wards were established for the insane in general hospitals it would be a comparatively easy matter to determine quickly which patients required a lengthy course of treatment, and the fact of thus being enabled to distinguish between the different degrees of madness, and to treat accordingly, would be at once an act of humanity, and doubtless in the long run a saving to the general public. The partial irresponsibility of those given over to the alcohol or drug habit is now generally allowed, and the necessity of prompt emergency treatment for this unfortunate class cannot be ignored. Drug or alcohol habitués refuse to enter a hospital for the insane, but the majority of them would gladly avail themselves of the opportunity afforded of temporary treatment and care in a special ward of a general hospital. On the whole, therefore, the public-spirited plan about to be inaugurated at Albany Hospital will commend itself as one worthy of imitation by similar institutions not only in New York State but in all parts of the civilized world.

MEDICAL EDUCATION IN THE UNITED STATES.

So far as the number of schools of medicine is concerned, the United States will compare favorably with any country in the world. Excluding graduate schools there are, according to a monograph on professional education written by Mr. James Russell Parsons, Jr., 156 schools of medicine, 5,735 instructors, and 24,119 students. A foreigner reading this statement, and unacquainted with the facts of the case, would come to the conclusion that medical education in this country was in a particularly healthy condition. If, however, he were of a curious disposition, and were to dive more deeply into the matter, his opinions would assuredly undergo a radical change. In saying this there is no intention to disparage the efforts made in the country generally to improve the standard of medical education, or even to assert that these efforts have not been attended with a fair measure of success. The defect in the present system is the apparently needless multiplication of standards, and until effective means have been introduced to bring about some sort of uniformity in the standards, medical education will stand on no solid foundation. Mr. Parsons is of the opinion that a uniform standard for admission to practice throughout the United States is impracticable at present, owing to varying conditions as to density of population, educational advantages, and general development, and recommends that, instead of the adoption of a separate standard for almost each political division, two, or at most three, standards should answer for all.

The existing easy-going methods of granting degrees in medicine prevailing in many States has the effect of flooding the market with medical men, with correspondingly disastrous competitive results. For example, quoting again from Mr. Parsons' monograph, the ratio of physicians to population is one to less than six hundred in the United States, while in foreign countries it varies from one to about eleven hundred in the British Isles to one to about eighty-five hundred in Russia. We are said to have in proportion to our population four times as many physicians as France, five times as many as Germany, and six times as many as Italy. There are more medical schools in the United States alone than in countries whose total population is six times as great, and yet few of these medical schools in the United States have endowments corresponding to those so lavishly made to other educational institutions or in any way proportioned to their needs. Fortunately a change would now seem to be indicated in the attitude of philanthropists toward medical schools. In New York the advanced requirements for license have been accompanied by extraordinary growth in the property of medical schools, especially in Greater New York. Indeed, without wishing to exalt unduly the accomplishments of the regents of the University of the State of New York, the fact must be recorded that owing to the foresight of this body professional education in New York State now stands on a higher plane than in any other State in the Union, and emphasizes the need of similar councils of education in the other political divisions.

FLEAS OF RATS AND MICE AS CONVEYERS OF PLAGUE INFECTION TO MAN.

WHILE evidence is rapidly accumulating to show that rats are the chief factors in the importation of plague into a country, opinions are at variance as to the danger to be apprehended to man from the fleas of rats and mice. Much has been written in support of the theory that it is possible for a human being to become infected by the plague germ through the agency of fleas which may have infested these vermin, but no satisfactory proofs on this point have been as yet produced. The fact has been demonstrated that fleas taken from a plague-stricken rat are capable of inoculating healthy rats or mice with the plague bacilli, but it must be borne in mind that there is a distinct difference between the flea of a man and that met with on rats and mice. Dr. Bruno Galli-Valerio, of Lausanne, in an article first published in the *Centralblatt für Bakteriologie*, etc., and reproduced in the "Public Health Reports" of the United States Marine-Hospital service of February 16, 1900, distinguishes these fleas as follows: "The flea of man (Pulex irritans) has an ovoid body, reddish-brown in color, and is without a comb upon the head or prothorax. The flea which most commonly infests rats (Typhlopsylla musculi) has a thin body, is yellowish in color, with spines upon each side of the inferior border of the head, and a comb upon the prothorax. Upon the mouse and marmot we also find the Pulex pasciatus, but it presents upon the prothorax a comb of eighteen points and has only been found, as I remember, in Holland and in Halle, and I myself have found it once in Milan." Therefore Dr. Galli-Valerio does not consider it as proven that the fleas of rats and mice may transmit the plague to man.

PURE FOOD LEGISLATION.

AT the present moment there are two bills before Congress whose aim is to prevent the adulteration of food products. The first of these is H. R. 4,618, introduced December 18, 1899, by Mr. Babcock, and the second is H. R. 6,246, introduced January 15, 1900, by Mr. Brosius.

Mr. Babcock's bill provides for the appointment of a food commissioner within the Department of Agriculture. The food commissioner shall, with the approval of the Secretary of Agriculture, appoint a chief chemist, who on his own responsibility shall appoint such chemists and other employees as shall be needed. The food commissioner shall make the requisite rules and regulations for the proper conduct of his bureau. The bill further defines the term "food," and indicates in a general way what shall be considered as adulterations. Section 8 provides "That the food commissioner may call upon the Association of Official Agricultural Chemists to determine the standard of any food products within the meaning of this act, and when so determined, such shall remain the standard before all courts." This is a curious provision, throwing much responsibility on a body which, though called "official," is simply a private association of persons holding official positions in different States. It apparently gives this body the power to determine the wholesomeness or otherwise of certain food products, a function that in no proper sense is within the province of a chemist. The clinical physician alone is competent to judge of matters of this kind, and it is to be regretted that chemists so often overstep the proper confines of their science and presume to offer opinions on subjects beyond their proper scope. We cannot too strongly commend to their attention the old saying: "*Ne sutor supra crepidam.*" Section 11 permits manufacturers, etc., of "compound mixed or imitation foods" to "certify, under oath," that they are "not deleterious or injurious to health," and on further payment of $10 permits the same to be registered by the Secretary of Agriculture. This is certainly an extraordinary provision. The other sections of the act relate to regulations necessary to its proper administration, and appear to us to be wise and judicious. The last section of the bill provides that the expenditures necessary to the carrying out of the act shall not exceed $100,000 in any one year.

We believe that the passage of this act with the omission of Sections 8 and 11 will be the beginning of a movement that in time will secure to the American public a reasonable guarantee as to the quality of the foods they consume. It must be remembered that Congress has power to legislate only in connection with interstate and foreign commerce, and that the various State governments must enact supplementary measures before the people will be properly safeguarded. We will consider the second or "Brosius" bill later.

THE STATUS OF THE ACTING ASSISTANT SURGEONS OF THE UNITED STATES ARMY.

THE civil surgeons whose aid it was found necessary to enlist during our war with Spain would appear to be extremely dissatisfied with the manner in which they have been treated, and are, moreover, bent upon ventilating their wrongs, with the view of having removed the disabilities from which this somewhat anomalous class of army doctors suffer. A mass-meeting of acting assistant surgeons was held at the armory of the Seventh Regiment in New York on December 5, 1899, at which one hundred and fifty of these gentlemen were represented in person, by proxy, or by letter. At this meeting a permanent organization was formed and a constitution and by-laws were adopted. The constitution reads as follows: "The object of the association shall be to maintain the patriotic and professional *esprit de corps* and *camaraderie* of the men who during the war between the United States and Spain held the position of acting assistant surgeon in the United States army, and to secure their rights and to protect their interests of every kind, especially those requiring legislation by the Congress of the United States."

The grievances under which the acting assistant surgeon now labors, in the opinion of the members of the organization, are that although an acting assistant surgeon is expected to fulfil in every respect the duties incumbent on the regular army surgeon, yet he is debarred from sharing in the privileges and emoluments accorded to the latter. He does not rank as an officer. When an acting assistant surgeon is wounded or killed in action or stricken down by disease while on duty, no provision is made for his care or support in the event of such occurrences. If sick while on duty, his pay is immediately stopped, and no provision is made for feeding him, for sheltering him, for giving him medical attention, or for bestowing on his dead body any of the care accorded to the military dead; and lastly, an acting assistant surgeon is not eligible to receive a medal for "conspicuous bravery in the field."

It is also stated that there is a lamentable lack of harmonious feeling between the regular army surgeon and the contract surgeon. The lines therefore of the civil surgeon who volunteers his services in the time of war do not seem to be cast in pleasant places, and the inducements offered are not sufficiently attractive to render his position one to be ardently desired. The old contract system might be with advantage, if not entirely abolished, at least considerably modified. It would appear but reasonable that during the time that an acting assistant surgeon serves in the army, performing to the best of his ability all the duties required of a regular army surgeon, he should be entitled as far as is possible to the same privileges and emoluments. If perchance this country should be suddenly plunged into a large war, the services of civil surgeons would necessarily be again requisitioned. Would it not be better policy to place the status of these men on a satisfactory footing than to continue an out-of-date and unpopular system?

News of the Week.

Crowded Professions in Cuba. — The Cuban cabinet has decided to adopt the recommendations of Señor Barreiro, secretary of public instruction, for the reorganization of the School of Engineers, in order that young men may be able to adopt some other profession than law and medicine, both of which are overcrowded. The Spaniards founded an engineering school, but when they found that the graduates were competing with Spanish engineers the school was neglected to such an extent that it became valueless. It will now be raised to a high standard of efficiency.

A French Institute for the Study of Tuberculosis.—The Société Lyonnaise des Tuberculeux Indigents has undertaken to build an institute for the study of phthisio-therapy, which it proposes to make an annex of the free sanatorium which it is about to open at Hauteville. It is now suggested that the undertaking be made a national one, and with this end in view a bill has been introduced into the French Senate making an annual grant of 15,000 francs to further the work of the institute.

The Anglo-American Nursing-Home in Rome.— Efforts have been making for some time to establish in Rome a nursing-home, in which persons of British or American nationality who have the misfortune to fall ill in the Eternal City can be received. The scheme met with opposition in certain quarters, but *The British Medical Journal* announces that all difficulties have now been successfully overcome. A *villino* excellently adapted for the purpose was found in the Via Nomentana, a little way outside the Porta Pia. The building is charmingly situated, standing well back from the road, in about half an acre of ground. Round about it are pretty villas, each isolated in its own ample garden, and there is no fear of the surrounding open spaces being built over. The house has twenty-seven rooms, and can conveniently accommodate six or eight patients, who have the use of several comfortable day-rooms. The walls and ceilings are artistically painted, and all the rooms have a cheerful outlook. On the roof is a terrace commanding an extensive view of the Campagna, with the whole range of the Alban and Sabine hills in the distance.

Ordinary patients pay an inclusive charge of twenty francs a day, but two beds are set apart for patients who cannot afford more than half the usual rate, and two are entirely free. The home, which was opened in the early part of January, is at present partly dependent on subscriptions, but it is hoped that it will soon be self-supporting. Miss Gibbons, who was formerly matron of the Tewkesbury Cottage Hospital, has accepted the post of directress, without salary. Patients can be sent in by any medical practitioner in Rome, and remain under his charge while in the home.

Transactions of the International Medical Congress.—The secretary-general of the Thirteenth International Medical Congress writes to Dr. Jacobs, secretary of the American National Committee, that, as there has been some misunderstanding about the sectional arrangements, it should be known that every member may join as many sections as he pleases for a single subscription, but that the expense will prevent every member receiving a copy of the whole twenty-four volumes of the Transactions of the Congress, as it is intended to issue a volume of the work of each section. Each member of the Congress will receive therefore (1) a volume containing a general summary of the work of the Congress, (2) a volume containing a full report of the general sessions of the Congress, (3) a volume containing the work of the section to which he chooses to affiliate himself. If a member has joined several sections he will receive the Transactions of the section which he has placed first on his form of application for membership. Members of the Congress who wish to receive the whole set of transactions should communicate with M. Masson, the publisher, 120 Boulevard St. Germain, Paris. The greater the number of volumes ordered by any congressist the less will be the price of each volume.

The Samuel D. Gross Prize of the Philadelphia Academy of Surgery.—The conditions annexed by the testator are that this prize of $1,000 "shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in surgical pathology or surgical practice, founded upon original investigations, the candidates for the prize to be American citizens." It is expressly stipulated that the competitor who receives the prize shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D. Gross library of the Philadelphia Academy of Surgery, and that on the title-page it shall be stated that to the essay was awarded the Samuel D. Gross prize of the Philadelphia Academy of Surgery. The essays, which must be written by a single author, in the English language, should be sent to the "Trustees of the Samuel D. Gross prize of the Philadelphia Academy of Surgery, care of the College of Physicians, 219 South Thirteenth Street, Philadelphia," on or before October 1, 1901. Each essay must be distinguished by a motto, and accompanied by a sealed envelope bearing the same motto, and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. None of the essays received on January 1, 1900, was deemed by the trustees worthy of the prize.

The American Academy of Medicine.—The twenty-fifth annual meeting of this society will be held at The Shelburne, Atlantic City, on Saturday, June 2d, and Monday, June 4th, just preceding the meeting of the American Medical Association. The president is Dr. G. Hudson Makuen, of Philadelphia. The subject of the annual symposium is "The Medical Aspects of the Home."

Philadelphia Neurological Society.—At a stated meeting held February 26th, Dr. A. P. Francine presented two cases of tabes dorsalis in negroes—husband and wife. The symptoms had appeared first in the husband, who admitted a history of syphilis, and in whom there was a remote admixture of white blood, while the wife presented evidences of considerable admixture. Dr. C. W. Burr presented a case of lesion of the spinal cord following injury to the neck. The patient was a woman presenting right hemiplegia, with a tendency to contractures and easily induced and persistent patellar clonus, and impaired thermal sensibility. The symptoms had developed in the sequence of a fall. Dr. Wharton Sinkler presented two cases of paralysis agitans. In one the tremor was violent and confined to the right hand, while the face was mobile. The other was of long standing, the symptoms developing many months after an injury. The patient exhibited marked propulsion and retropulsion, and was able to walk better over obstacles than upon the level. He could perform few movements deliberately, but upon sudden impulse and under emotional strain he was able to do much better. A deformity of the spine had been discovered and an operation had been performed, the statement being made that a fracture of a transverse process of the second lumbar vertebra had been found. The patient thought the symptoms had been stationary subsequent to the operation, but the evidence pointed to the fact that they had progressed. Dr. Joseph Sailer presented a case of paralysis of the left upper extremity with astereognosis. The patient had had several convulsive seizures, with transitory loss of consciousness, and he presented physical evidence of valvular disease of the heart. The lesion was thought to be situated in the arm centre in the right cerebral hemisphere, and to be of vascular origin, but the discovery of bilateral neuro-retinitis raised the question of a new growth. Dr. Henry J. Berkley read a paper on "The Pathological Findings in a Case of General Cutaneous and Sensory Anæsthesia." The patient was a middle-aged woman who had been under observation for some ten years, and presented not only widespread cutaneous anæsthesia, but also abolition of all of the special senses. Post-mortem examination disclosed intense thickening of the vessels generally, with diminution in calibre, and slight degeneration in various parts of the nervous system. Dr. Berkley exhibited a specimen of false porencephaly in a rather unusual location. The patient had been a medium-grade imbecile, without symptoms of focal disease; but upon post-mortem examination a deficiency in the brain structure was found on the median and inferior aspect of one hemisphere. More careful investigation showed this to be due to an extravasation of blood from a ruptured vessel. Dr. C. W. Burr presented a case of general cutaneous anæsthesia, with partial loss of painful sensibility. The patient was a man of low intelligence, who presented, besides, symptoms suggestive of hysteria. Dr. W. G. Spiller made a brief report of a case in which there was bilateral optic neuritis, with abolition of the function of the remaining cerebral nerves upon one side.

University of Pennsylvania, Class of '75.—An effort is being made to secure a reunion of the University of Pennsylvania, medical class of '75, at the coming commencement in June. Every member of this class is requested to send his address and a brief account of his doings since graduation to Dr. Charles W. Dulles, 4101 Walnut Street, Philadelphia.

College of Physicians of Philadelphia.—A stated meeting was held on March 7th. Dr. Frederick A. Packard read a report of a case of ostitis deformans (Paget's disease). Dr. John H. Musser read a paper entitled "The Antitoxin Treatment of Diphtheria," in which he reported a series of cases treated by this means without a death, and some of which it was thought would have terminated fatally if other measures had been used instead. Dr. Edward P. Davis read a paper entitled "The Differential Diagnosis of Ectopic Gestation, with a Report of Cases." Dr. W. W. Keen exhibited a new kind of material for sutures and ligatures made of celluloid, and which commends itself on account of its cheapness and its susceptibility of sterilization by all of the easily employed methods. Dr. Keen also exhibited the specimen from a case of ligation of the abdominal aorta. The vessel was tied just below the diaphragm with several strands of silk, and the patient survived for forty-eight days, death resulting from hemorrhage due to cutting through of the ligatures. On post-mortem examination the condition was found to be a false aneurism.

Pathological Society of Philadelphia.—At a stated meeting, held March 8th, Dr. A. O. J. Kelly read a communication on "Tumors of the Vermiform Appendix," and exhibited sections of endothelioma and carcinoma of this organ. He related that among nearly eight hundred vermiform appendages examined systematically following operation, in four only were new growths found, and none of these had been suspected during life. Three were carcinomatous and one was an endothelioma. Dr. C. H. Frazier presented a communication entitled "Vermiform Appendix Containing Oxyures Vermiculares." The patient had presented symptoms of appendicitis, and after removal the appendix was found to contain a considerable number of living seat-worms. Dr. G. G. Davis reported a case in which a segment of tape-worm was found. in a removed appendix. Drs. De F. Willard and W. G. Spiller reported a case of cyst of the inguinal region, and presented numerous foreign bodies removed therefrom. Some doubt existed as to the nature of the cyst, but it was thought to represent a collection of so-called free bodies, such as form in cavities lined by endothelium, although the possibility of its being a dermoid cyst was considered. Drs. Blackwood and Dr. W. G. Spiller reported a case of cerebro-spinal syphilis, and presented the specimens, which exhibited a marked degree of arteritis and cavities in the substance of the brain. Dr. D. J. McCarthy presented the brain from a case of adiposis dolorosa, exhibiting a tumor of the pituitary body obstructing the orifices of the ventricles and causing considerable internal hydrocephalus. The patient had presented no symptoms of acromegaly.

The Medical Club of Philadelphia tendered a reception on March 8th to Dr. Charles G. Stockton, of Buffalo.

The Boer Army Surgeons.—It is stated that two-thirds of the surgeons in the Boer army are either Germans, or Afrikanders educated in Germany. Two of the Germans, Drs. Hohls and Coster, have been killed while assisting the wounded on the battlefield.

An Example for Philanthropists to Follow.—A philanthropist of Palermo, Signor Ignazio Florio, recently founded a dispensary for diseases of the eye, in which all the poor are treated without cost. But this is done at the expense of the institution and not of the attending ophthalmologists, each of whom receives regular fees for the cases treated at the same rate as if they were cases in private practice.

An Epidemic of Typhoid Fever is prevailing at Milton, Pa., over one hundred cases being believed to exist, and the physicians are unable to check the spread of the disease. Among the deaths are those of Dr. Clark and Dr. Sticker. The epidemic is attributed to the city's water supply, which is derived from the Susquehanna River.

Faith Cure and Keeley Cure.—Our attention has been called to a palpable error of statement made by a correspondent (Medical Record, December 23, 1899, p. 949) referring to cases of insanity following the so-styled Keeley cure for alcoholism. It should read "faith cure" instead of "Keeley cure." We say this in justice to the alleged claims of the latter, although we are free to confess that neither mention is entitled to any scientific consideration.

The New York Medical League.—The report of the committee on charities and legislation of the Manhattan section of this society was presented at the last annual meeting. We learn from this that the League was active in securing the passage of the dispensary law by the legislature. It was also instrumental in preventing the grant of a certificate of incorporation of the Home for Patients with Incurable Cancer and of the Emanuel Hospital.

Mania a Sero.—A severe epidemic of a new form of insanity appears to be setting in. With *mania a potu* medical practitioners are already sufficiently familiar; now we are beginning to make acquaintance with *mania a sero*. This remarkable affection does not attack the patient but the physician, and the symptoms are particularly severe in those who themselves make the serum. The victims of seromania suffer from extraordinary delusions, under the influence of which they appear bereft of the power of judgment, and mistake their own fancies for facts. It is only on this hypothesis that one can explain the amazing statements made in all good faith by men whose scientific training should have made them capable of seeing things as they really are.—*The Practitioner.*

Typhoid Fever at Ladysmith.—Mr. Treves reports that he entered Ladysmith on March 2d and found the health conditions in the town most deplorable, the number of cases of typhoid fever being eight hundred.

"Bibliographia Medica."—This is the title of a successor to the *Index Medicus*, published in Paris under the direction of Drs. Potain and Richet and the editorial management of Dr. Marcel Baudouin. The work will appear the 15th of each month, and the subscription price is 60 francs ($12) outside of France.

Gratitude was shown in a substantial manner to Dr. Linder, the house surgeon of the Society of the Hebrew Orphan Asylum of Brooklyn, at a recent meeting. A purse was voted him as a testimonial of faithful work during a recent epidemic of diphtheria. That his work was probably also efficient would appear from the fact that though twenty-three cases were treated, there were no deaths.

The Louisiana State Medical Society.—The twenty-first annual meeting of this society will be held at the Tulane University Medical School, New Orleans, on April 19th, 20th, and 21st, under the presidency of Dr. W. G. Owen, of White Castle. The work of the meeting will be distributed over fifteen sections. In the section on diseases of children the subject for discussion will be "Measles and Smallpox in Children."

The Orange Practitioners' Society was organized on March 2d, at Orange, N. J., with a membership of twenty. A constitution and by-laws were adopted and the following officers were elected: *President*, M. Herbert Simmons; *Vice-President*, Edgar Calvin Seibert; *Secretary and Treasurer*, Walter M. Dodge; *Executive Committee*, Arthur W. Bingham, Francis E. Knowles, and Thomas N. Gray. The society will meet on the first Friday in each month at the residences of its members.

A Sicilian Sanatorium for Consumptives.—Signor Ignazio Florio, a wealthy merchant of Palermo, has recently built a sanatorium for consumptives which is said to be a model of sanitary perfection. It is on the shore to the north of Palermo, and faces south, Monte Pellegrino protecting it at the back from the north winds. The building is constructed of fireproof material, with iron and concrete flooring. The corners of the rooms are rounded, there are no mouldings and no projecting decorations, and the walls are smooth and painted. The patients' rooms all face the sea, and each has its own bathroom and toilet arrangements. The laundry and disinfecting-plant and the chemical and bacteriological laboratories are housed in separate buildings. The drainage system has been constructed with particular care, and excrementitious matter is sterilized before being discharged into the sea. The sanatorium is under the medical direction of Dr. Vincenzo Cervello, of Palermo, who has a staff of assistants. The sanatorium is for those who can afford to pay for luxury, but seventy-five per cent. of the net profits will be devoted to the maintenance of other sanatoria for the poor.

A Medical Society Dispensary.—The Society of Russian Physicians in Moscow manages a dispensary in which 26,240 patients were treated in 1899.

A History that Repeats Itself.—Four-year-old Matilda Neiman contracted diphtheria. A Christian scientist visited her. The house was not placarded. People came and went. Matilda died. Coroner Loyd investigated. Verdict, neglect. There are other cases in that neighborhood now.—*The Stylus.*

Mütter Lectureship of the College of Physicians of Philadelphia.—The next course of ten lectures instituted by the late Prof. Thomas Dent Mütter, M.D., LL.D., on some point or points in surgical pathology, will be delivered in the winter of 1902–1903 before the College of Physicians of Philadelphia. The compensation is $600. The appointment is open to the profession at large. Applications, stating in full subjects of proposed lectures, must be made before October 1, 1900, to the committee on the Mütter Museum, John H. Brinton, M.D., chairman, northeast corner of Thirteenth and Locust streets, Philadelphia, Pa.

The Plague.—It is curious to note the senseless panic that seems to seize even physicians whenever plague is mentioned. Last week in San Francisco a Chinaman died, and somebody suggested that the cause of his death might have been pest. Immediately a cordon was placed around Chinatown, and a quarantine was maintained for several days until the health authorities found that the case was probably not one of plague. In the mean time cooks and other servants in hotels and private houses were kept from their work, and the community was duly scared.—A Japanese steamer is held in quarantine at the Diamond Head station near Port Townsend, about seventy miles from Vancouver, because of a death from plague which occurred on board during the voyage. It is said that several cases of alleged beri-beri on Pacific steamers have been found to be of the plague.—Reports from Honolulu, dated March 2d, state that sporadic cases of plague continue to occur there and on other islands of the group. The executive council in Hawaii has been authorized to expend $300,000 in furthering the effort to stamp out the plague there.—In Calcutta the disease is increasing, there having been four hundred and eleven deaths from the disease there during the first week in March.—From Cape Town a dispatch states that a case of plague occurred on a vessel arrived there from Rosario and Buenos Ayres. From the latter city a telegram, dated March 7th, announced that a number of cases of what is supposed to be the bubonic plague have been officially reported. Urgent measures are being adopted to prevent the spread of the disease.—Three new cases of the plague were reported in Sydney, N. S. W., on March 11th.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending March 10, 1900. March 2d.—Medical Director J. C. Wise commissioned medical director from February 7, 1900. Medical Inspector E. Z. Dorr commissioned medical inspector from February 7, 1900. Surgeon R. P. Crandall commissioned surgeon from September 24, 1899. Assistant Surgeon J. T. Kennedy appointed assistant surgeon. March 7th.—Medical Inspector G. E. H. Harmon detached from the *Baltimore* and ordered to the *Oregon*. Surgeon F. B. Stephenson detached from the *Oregon* and ordered to the *Baltimore*. Assistant Surgeon W. B. Grove detached from the *Brooklyn* and ordered to the *Baltimore*. Assistant Surgeon H. H. Haas detached from the *Brooklyn* and ordered to such other duty as the commander-in-chief of the Asiatic station may assign. March 8th.—Passed Assistant Surgeon J. C. Rosenbleuth detached from the naval recruiting rendezvous, New Orleans, La., and ordered home and to wait orders. Assistant Surgeon F. E. McCullogh detached from the *Nero* when put out of commission and ordered to temporary duty on the *Independence*. Pharmacist I. N. Hurd ordered to additional duty on the *Massasoit*, Key West, Fla.

Obituary Notes.—DR. FREDERICK WILLIAM HECKER died at Spring City, Pa., on March 3d, at the age of seventy-one years. He was graduated from the medical department of the University of Pennsylvania in 1849. He was commissioned assistant surgeon in the Fifth Pennsylvania Cavalry in 1862, and in a little while was made surgeon in charge of the One Hundred and Sixty-fifth Pennsylvania Infantry.

DR. WILLIAM L. SMITH died suddenly at York, Pa., on March 4th, at the age of sixty-four years. He was a graduate of the medical department of the University of Pennsylvania, and he served through the civil war, having charge of the division hospitals of Generals Kearney and Geary during the campaign of the Peninsula of Virginia.

DR. OLIVER PAYSON HUBBARD died at his home in this city on March 9th, at the age of ninety-one years. He was born at Pomfret, Conn., and studied at Hamilton College and at Yale. He was graduated in arts from Yale College in 1828, and became the assistant of the elder Professor Silliman. He received his medical degree from the Medical College of the State of South Carolina in 1837. He was for many years professor of chemistry and pharmacy at Dartmouth College, and was retired as professor emeritus in 1883. He was for many years corresponding secretary of the New York Academy of Sciences.

DR. AARON EDGERTON PECK died at his home in Brooklyn on March 8th, at the age of sixty-five years. He was a graduate of the College of Physicians and Surgeons in this city in the class of 1855.

DR. WILLIAM GLATZMAYER died at his home in Newark, N. J., on March 6th, at the age of forty-two years. He was born in Brooklyn, and was graduated from the medical department of the University of New York in 1885. He was an alderman in Newark, having been elected in 1898.

DR. ISRAEL PRIOR died at his home in North Stamford, Conn., on March 6th, after a prolonged illness, at the age of fifty-eight years. He was graduated from the Bellevue Hospital Medical College in 1865, and began practice in Illinois, but later removed to North Stamford.

Progress of Medical Science.

Medical News, March 10, 1900.

Milk Inspection by the New York Board of Health.—Herman Betz makes a brief statement of the routine milk inspection in New York City. The milk inspector is appointed from the head of the list after passing a successful civil-service examination. He is on duty technically all the time, for he may be called upon at any hour, Sundays included. The relations between milk dealer and milk inspector are far more cordial than would be supposed, for the department of health is always fair. The inspector spends from 9 A.M. to 4 P.M. in actual inspections, after which a carefully detailed report is written out and handed in promptly to the chief inspector. The inspector carries with him a satchel containing suitable instruments and utensils. The samples of milk are taken to the laboratory of the department and examined. The analysis consists of the following factors: Water, per cent.; total solids, per cent.; fat, per cent.; solids, not fat, per cent.; per cent. low in solids; per cent. low in fat; borax, present or absent; salicylic acid, present or absent; formaldehyde, present or absent; reaction, acid or alkaline. Since 1896 the department has required every milk-dealer to take out a permit. There is an arrangement by means of which information from the various boards of health of the States from which milk is shipped to New York is sent to the New York board, concerning any contagious or infectious disease in those sections from which the milk comes. This is often of the greatest service in preventing the spread of disease.

A Case of Brain Tumor, with Exhibition of Specimen.—Hugh T. Patrick reports this case. The patient was a man thirty-five years old. He had several apoplectoid attacks which were followed by impairment of the use of the right arm. He had most of the mental symptoms of general paresis. His pupils were equal and normal in every respect. On account of the distinctly focal character of the paresis of the right arm, particularly, the author believed this a case other than general paresis. Active syphilitic treatment improved the patient considerably, especially as to his mental condition. The diagnosis lay between general paresis and brain syphilis. The former was excluded because he grew no worse, and because the symptoms of paresis had cleared up considerably under specific treatment. After his death, the brain was examined, revealing a growth of the nature of a glioma which was most intimately associated with the brain substance itself.

Observations on a Spirillum Occurring in False Membrane on the Tonsil.—Charles F. Craig, before describing the case that he reports, enumerates the spirilla which have been found associated with man. They are: Spirillum choleræ Asiaticæ; spirillum Obermeieri; spirillum of Finkler and Prior; spirillum sputigeneum of Miller; spirillum dentium of Arnt; spirillum or vibrio nasale of Weibel; spirillum of Miller. The case which Craig reports is that of a young man who complained of difficulty in swallowing and soreness of the throat on the right side. On examination the right tonsil was seen to be enlarged, slightly reddened, and covered with a thick, dirty white membrane occupying the posterior part and extending to the surrounding mucous membrane of the fauces. Cultures were taken from the membrane and a spirillum was obtained, the chief points of which were its large size, extreme activity, decolorization by Gram, and its occurrence in almost pure cultures in a false membrane of which it formed a considerable part, and in the crypts of the diseased tonsil. The case is of further interest because of the resemblance of the false membrane to that of diphtheria, and as showing the value of a microscopical examination of the exudate in all tonsillar affections.

Surgery of the Epiphyses.—Charles L. Scudder declares that many of the epiphyseal separations are mistaken for fractures in the neighborhood of the epiphyses. The Roentgen ray is revealing with a great degree of accuracy the lesions after traumatism to joints. The author gives great praise to John Poland's book upon the traumatic separation of the epiphyses, published in 1898. In conclusion, he reports four cases of surgery of the epiphyses.

Recent Methods in Cardiac Therapeutics by Baths and Exercises.—By Thomas E. Satterthwaite. See Medical Record, vol. lvii., p. 255.

A Unique Case in Obstetrics.—By Frederick H. Parker. See Medical Record, vol. lvii., p. 212.

Boston Medical and Surgical Journal, March 8, 1900.

The Gastro-Intestinal Tract in Nervous Diseases.—F. Savary Pearce holds that there are three classes of disease in which the nervous system is more or less intimately influenced by gastro-intestinal disorder and usually of a toxic nature: 1. (*a*) Neurasthenic states, general or in localized areas of distribution; (*b*) when organic changes are present in the nerve cells. 2. Cases when long-continued gastro-enteritis causes organic change in the mucosa and gastro-intestinal glands. 3. A mixed class of cases in which neurasthenia or organic nervous diseases are associated *pari passu* with disorders of digestion of a functional or organic nature.

A Method of Determining the Digestive Power of Gastric Juice as well as the Absorptive Power of the Stomach.—A. E. Austin describes his method and submits a table of experiments, by which we find these peculiar combinations: We may have good absorption, good digestive power, and deficient motility, or we may have another combination of poor absorption, fair digestive power, and deficient motility. These three factors once determined, in connection with the determination of the amount of rennin, make up an analysis which apparently affords us about all that chemical examination offers in the analysis of the stomach contents.

Remarks on the Influence of Technique upon the Results of Closure of Wounds of the Abdominal Wall.—Charles P. Noble prefers tier sutures to through-and-through sutures, and uses silkworm gut of a light weight as a buried suture, observing rigid asepsis, tying the sutures without tension, making the knot with three ties and cutting the ends off short. He describes his method of closing wounds, washing the wound repeatedly with salt solutions as layer after layer is closed. He uses the permanganate of potassium and oxalic acid method of disinfecting the hands, and wears rubber gloves.

Two Cases of Thomsen's Disease, and One of Transient Myotonia, Occurring in One Family.—S. A. Lord reports these cases from the neurological department of the Massachusetts General Hospital.

Abstract of Paper on "Further Experience of the Operative Treatment of Anteflexion."—W. L. Burrage reviews his notes of ninety-two cases of operation performed for anteflexion.

Journal of American Med. Association, March 10, 1900.

Some Points in the Diagnosis of Traumatic Injuries of the Central Nervous System.—J. T. Eskridge calls attention to the fact that damages are sometimes recovered from corporations for the effects of disease existing many years before the occurrence of the accident on which suit is brought. For this reason the railroad surgeon should make systematic examination of the injured as soon after the accident as possible. Persons who are severely injured are anxious for treatment and communicative, and a carefully gleaned history will often reveal that the subject had been hysterical, neurasthenic, or a sufferer from intrapelvic trouble prior to the injury. It must be borne in mind that the presence of one positive sign of organic trouble is of more importance for diagnosis of an organic lesion, than the presence of many symptoms, functional in character, in justifying us in excluding organic disease.

Treatment in Compound, Compound Comminuted, and Non-Union or Ununited Fractures.—C. D. Evans describes a contrivance for the treatment of fractures, especially ununited fracture. He reports a case of fracture of the lower third of the leg successfully treated by this means. The only material used by the writer to secure bony apposition is catgut No. 3, and the splint is formed from what is known as "band iron," which can be found at any tinshop and easily bent and moulded. Great stress is laid upon aseptic dressing of the wounds.

Treatment of Minor Traumatisms.—R. Harvey Reed insists upon the importance of handling the smallest minor injury with the same precaution as though it were a major one. He sums up the rules for the successful treatment of this class of traumatisms as follows: (1) Strict observance of surgical cleanliness; (2) preservation of normal blood supply; (3) perfect coaptation when possible; (4) simplicity and efficiency of dressings; (5) the use of chemicals which will destroy infective germs but will not irritate or disturb cell reproduction.

A Contribution to the Surgery of the Common Bile Duct.—John E. Summers reports a case of choledochenterostomy. The patient, a young woman aged eighteen years, reports herself as being in perfect health, having gained eleven and one-half pounds since the operation. The author says that, so far as he has been able to discover, this is the only reported American case of an anastomosis between the common bile duct and the bowel, although some of the latest text-books mention that such an operation may be done.

Hysterical Lethargy, with Report of Cases.—G. W. McCaskey says that after eliminating chronic auto-toxæmic processes in cases of somnolence or stupor, there still remain a large number which, so far as we know, are not toxic in their origin. Their nature is often obscure, although they can for the most part be regarded as either hysterical or epileptic in character. The writer reports several cases of hysterical origin. The treatment of these cases, aside from electricity and other forms of stimulation to the hysterogenic zone, is that of the hysterical state which forms its background.

Nervous Depression as a Sequel of Influenza.—B. J. Byrne calls attention especially to two features of this depression which he does not think are found associated with any other disease—namely, the subnormal temperature and the reduced pulse rate. In the cases of which he has kept records the temperature ran from 97° to 95° F., and the pulse from 60 to 48, for weeks and months. The medical treatment, consisting of strychnine in full doses (gr. $\frac{1}{20}$ of the sulphate three times a day), was somewhat unsatisfactory. The best results were derived from absolute rest.

Treatment of a Common Cold.—Frank Woodbury thinks that the "neurotic element" in a common cold has been too largely ignored in the plans of treatment usually followed. With the view of acting directly on this neurotic element he has for the last two years used the following combination: Pulv. morphinæ comp., gr. xx.; acetanilidi, gr. vi.; sodii bromidi, gr. x. This is divided into twelve capsules, of which one is taken every half-hour for two hours, then one every two hours. The writer has found that this will usually break up a cold in a few hours.

Dangerous Pulmonary Hemorrhage in Tuberculosis and its Management.—Norman Bridge says that in a severe hemorrhage the measures to be resorted to should have for their purpose the immediate lessening of the blood pressure. To this end the patient should keep as still as possible and avoid taking deep breaths. The bowels should be kept open and the clothing be loose. Of all measures, the writer thinks that morphine, preferably with a proportionate admixture of atropine, administered hypodermically, gives the most valuable results.

Insanity and the Turkish Bath.—Charles H. Shepard thinks that among the constitutional agencies in the treatment of the insane the bath should stand high, and that of all baths the Turkish bath is preeminent. The author says that while few asylums in this country have Turkish baths, much has been done in this way in Great Britain and Ireland to the great improvement in the statistics of cures, and also in the death rate.

An Intestinal Anastomosis in a Case of Tuberculous Fecal Fistula of Twenty Years' Standing.—In this case, reported by Jacob Frank, the anastomosis was performed with a one-inch Frank's decalcified bone coupler. In spite of an extremely severe condition very good union took place within a comparatively short time.

Description of a Case of Oral Surgery.—G. V. I. Brown reports this case, and submits photographs showing the extreme degree of disfigurement resulting from a burn, as also the extraordinary cosmetic improvement following operative interference.

Hygiene of Public Schools.—C. F. Ulrich considers this subject under the heads of ventilation, light, water supply, playgrounds, and prophylactic measures against contagious and infectious diseases.

New York Medical Journal, March 10, 1900.

Results of Hot-Air Treatment in Rheumatism and Gout.—L. A. Coffin describes the apparatus most commonly used in this country. It has been employed in the various forms of chronic rheumatism, tuberculous joint inflammations, sprains, synovitis, tendosynovitis, neuralgia, and club-foot. Various clinical histories from the experience of others are given, and the author cites two personal cases. He thinks that the superheated air acts by producing a profuse sweating of the part, carrying off immediately many waste products resulting from increased activity about the joint. It also increases cell activity and secondarily stimulates the general system.

The Direct Examination of the Larynx in Children.—Thorner figures various forms of lingual depressors which have been devised for this purpose. Difficulty in examination may arise from subjective causes due to the age of the patient, or may be due to the anatomical conditions present in the infantile larynx. He does not think that any of the instruments or methods described can be considered perfect, but they are an advance over our previous helplessness with this class of patients. The paper considered as a whole is an interesting *résumé* of the history of this special procedure in laryngology.

Some Home-Made and Homely Appliances.—J. Leverett commends the use of large manila-paper envelopes for the reception of all infected dressings, etc. The whole can then be burned. As a substitute for the Kelly obstetric pad he employs a circular tube of canvas containing the inner tube of a bicycle tire which can be inflated with the ordinary pump. To the canvas can be attached by a hook-and-eye device an ordinary rubber sheet. The whole can be deflated after use and packed in a small pocket.

Perineal Lacerations in Country Practice.—H. H. Wilson commends double episeotomy and the immediate repair of slight lacerations. Deep complete lacerations should wait for the secondary operation.

Six Cases of Chronic Heart Disease Successfully Treated by the Schott Method.—Histories of the cases are given by V. Neesen, who includes a description of the method and a diagrammatic plan of the Schott exercises.

Report of a Case of Double or Twin Uvula.—The case occurred in the practice of L. S. Somers, the patient being a woman aged twenty-five years. The author adds some remarks upon abnormalities of the uvula and their relation to other lesions of the upper air tract and to the system at large.

Shock and its Surgical Significance.—By J. H. Rishmiller. A continued article.

Philadelphia Medical Journal, March 10, 1900.

Arteriosclerosis.—Joseph Eichberg gives the etiology, symptomatology, and treatment of this affection. The main causes mentioned are physical overwork, mental strain, poisons—lead, tobacco, and possibly alcohol—and overeating combined with a sedentary life. The treatment consists in the removal of the cause as far as may be possible, the application of the Schott method, and the administration as needed of the nitrites and iodide of sodium.

A Case of Gastrotomy for a Foreign Body in the Stomach.—George G. Hopkins describes the case of a dime-museum performer from whose stomach he removed a collection of miscellaneous metal articles. See MEDICAL RECORD, vol. lvii., p. 109.

The Surgical Use of Celluloid Thread.—W. W. Keen and Randle C. Rosenberger describe a number of experiments demonstrating the value of this suture and ligature material devised by Pagenstecher.

Double Fracture of the Clavicle. Gunshot Wound of the Lower Portion of the Spine, Producing Paralysis of the Area Supplied by the Fifth Sacral Nerve.—W. H. Hudson reports cases of these injuries.

A New and Simple Breast Binder for Post-Partum Use.—Joseph Brown Cooke describes and pictures an improvement on the Murphy binder.

Some Old Certificates of Proficiency in Medicine.—Francis R. Packard makes a contribution to the history of medicine in North America.

Selection from the Lane Lectures.—A portion of a lecture on diseases of the arteries, by T. Clifford Allbutt at Cooper College in 1898.

The Lancet, March 3, 1900.

The Treatment of Some Forms of Appendicitis at Plombières without Operation.—Skene Keith states that at the spa mentioned, chronic appendicitis is treated by daily baths, the patient lying covered to the neck in water at 35° C. Baths last for forty minutes. After the first few baths and for the last ten minutes of the later ones, a feather-like douche of warmer water is applied to the region of the appendix. Care must be taken to regulate the force of this douche. After the bath the patient rests for half an hour or so. The cases of appendicitis best adapted to the treatment are those due in part at least to some general condition.

On the Relation of Blood to the Lymphatic Vessels.—C. H. Leaf illustrates by diagrams the various ways a vein can communicate with a lymphatic. These communications allow malignant cells to pass from one set of vessels to the other in either direction. Hence in sarcoma and carcinoma alike the veins should be looked upon as possible channels of contagion.

A Case of Suppression of Urine of Sixty Hours' Duration Treated by Operation.—The patient seen by F. Jaffrey was a man, aged fifty-three years, supposed to be suffering from hydronephrosis. Operation showed the pelvis of the kidney full of blood clot. Secretion of urine began two hours after the operation was finished.

A Case of Leprosy.—The case described by J. D. Gimlette occurred in an Eurasian, aged twenty-seven years. The symptoms were obscure at the outset, the case being confounded with infective rheumatism, peripheral neuritis, and finally tertiary syphilis. Bacilli of leprosy were finally found.

Hallux Valgus and Hallux Varus.—J. Jackson Clarke defines these terms and gives their anatomical relations. For the former he advises complete exsection of the head of the metatarsal bone. He believes that every case is curable.

A Contribution to the Surgery of the Kidney.—L. W. Bickle gives histories of nephrectomy during the third month of pregnancy with recovery, followed by delivery at full term, and of nephro-lithotomy.

The Anatomy and Pathology of the Rarer Forms of Hernia.—By B. G. A. Moynihan. The third of the Arris and Gale lectures.

Tuberculous Disease of the Kidney; its Etiology, Pathology, and Surgical Treatment.—By D. Newman. A continued article.

Rabies.—By J. R. Bradford; a lecture delivered at the University of London.

The Medical Press and Circular, February 28, 1900.

Antral Catarrh and Suppuration.—J. G. Turner says the causes of antral suppuration are to be found in extension from neighboring sinuses and the nose. Third molars, acting as foreign bodies, may start antral suppuration. For transillumination the lamp must be placed centrally in the mouth and both sides compared as to (1) illumination of pupil; (2) appreciation of light by the patient; (3) amount of light coming through around the lower margin of the orbit; (4) amount coming through the cheek. Chronic cases are difficult of cure.

Radical Cure of Hernia.—P. G. Lodge records a case of epiplocele of six years' duration. An eight-inch incision was made over the tumor. A pound of adherent omentum was removed. The free edge was hemmed with catgut. An undescended testicle was at the same time removed. The muscular structures were stitched to Poupart's ligament. The limb was immobilized by poro-plastic felt down the front of the body and thigh. A complete cure resulted.

Tuberculous Trochanteric Disease.—J. Basil Hall bases a paper upon four cases reported. The deposit of tubercle is inside the line of junction between the trochanter and the bone, in the base of the neck of the femur rather than in the trochanter. In each case there seems to have been an ostitis round an old tuberculous sequestrum.

Vaginal Pessary in Uterine Erosion.—Alexander Duke presents a note on the use of the pessary as a help in the treatment of uterine erosion, and finds it an important factor of speedy cure.

Chronic Prostatitis. — H. Delagrammatica gives clinical notes of four cases of chronic prostatitis, each presenting points of interest.

The Dilatations and Diverticula of the Œsophagus.—By John Knott; a continued article.

Deutsche med. Wochenschrift, Feb. 15 and 22, 1900.

Cancer of the Large Intestine.—I. Boas discusses under this title the symptomatology and treatment of malignant disease of the colon. As regards subjective symptoms the cases fall into four classes: (1) those in which local signs are absent for a long time or throughout, the progressive cachexia being the only thing to arouse suspicion; (2) those in which the local symptoms are indefinite; (3) those of deep-seated stenosing carcinoma in which colicky pains are accompanied by tenesmus and strangury, as frequently seen in cases of rectal cancer; (4) cases in which symptoms of ileus appear in the midst of apparent health or after prodromes of not alarming character. Of greater value than the subjective symptoms is the presence of a palpable tumor. Contrary to the teaching of the text-books the tumor is not always movable. A movable tumor may temporarily escape the most careful palpation, and repeated examinations are therefore necessary. The occurrence of stricture is a symptom of the greatest value. Vomiting, hæmatemesis, constipation, diarrhœa, the shape of the formed dejections, and the presence of blood and pus in the stools, are signs, taken alone, of little positive value. The results of operative treatment have hitherto not been particularly encouraging, but with the possibility of earlier diagnosis will come that of earlier operation, and the prognosis will then be improved.

The Surgical Treatment of Renal Tuberculosis.—F. König says that two forms of renal tuberculosis must be recognized: (1) tuberculosis of the gland substance not communicating with the pelvis, and (2) the pyelitic form. The diagnosis of the first form is often impossible, but that of the second is usually quite easy even without the demonstration of tubercle bacilli. It is, however, not always possible to assure ourselves of the soundness of the other kidney. Resection of the kidney is scarcely ever to be thought of, and cystotomy also very seldom, in cases of renal tuberculosis, extirpation of the diseased organ being the only certain operation for the relief of this condition. This operation is indicated as a life-prolonging measure in a number of cases even when the other kidney is slightly affected and when the bladder, prostate, and testes are likewise diseased.

A Case of Sharply Circumscribed Cancer of the Stomach.—Herhold reports the case of a man who consulted him for the relief of severe gastric symptoms. Palpation revealed the presence of a hard movable tumor of the stomach. On operation this was found to be attached by a broad base to the mucous membrane of the stomach. The stomach was markedly contracted owing to the nominal quantity of food the man had taken for months previously. The growth was removed and the man made a good recovery, having gained remarkably in weight and strength in the four months which had elapsed between the operation and the date of the report. The tumor was confined to the mucous membrane, the muscular and serous tunics being absolutely free.

The Oliver-Cardarelli Symptom in Cases of Mediastinal Tumor. — Max Auerbach reports two cases of tumor of the mediastinum, one of enlarged mediastinal glands due to metastasis from gastric carcinoma, the other of cancer of the lung with metastases of the bronchial glands. In both of these tracheal tugging, a symptom alleged to be pathognomonic of aneurism of the arch of the aorta, was present.

Vaccination Technique.—Flachs covers the place of vaccination with sterilized gauze fixed by means of adhesive plaster, and covers all with a bandage. The child is bathed every day, and the bandage is changed after the bath. At the end of a week the gauze is renewed, being then spread with boric-acid ointment. By this method the production of a conspicuous scar is usually prevented.

Absorption and Elimination of the Iron of Iron Somatose in the Animal Organism.—W. Nathan describes the results of a number of experiments made by feeding this substance to mice, from which he concludes that it is actually absorbed when introduced into the intestinal canal.

Actual Dilatation of the Heart.—By Hans Herz. A continued article.

Berliner klinische Wochenschrift, February 19, 1900.

Auto-Intoxication.—C. A. Ewald discusses the question in the light of recent literature and clinical experience, devoting especial attention to the poisonous effects of the urine. He is inclined to think that the matter has been carried to too great a refinement of discussion in these later days, and that the modes of actual auto-intoxication are far fewer than is generally supposed. Many instances adduced as causative of disease are really the result of the latter.

Cæsarean Section.—According to H. Freund, perforation of the head of a living child is an unjustifiable procedure when there is no danger to the life of the mother, and when the surroundings are in the general sense favorable for the successful issue of a grave surgical operation. He does not consider the dangers of the operation greater than those of a complicated delivery, an ovariotomy, or an abdominal section with removal of the adnexa.

Observations on the Paper of H. Salomon on Brain-Pressure Symptoms in Typhus.—E. Stadelmann differs from Salomon, whose paper was published in No. 6 of the current volume of the *Wochenschrift*, and states that he does not approve of lumbar puncture in the condition named, his clinical experience having convinced him of its futility.

The Care of the Navel of the Newly Born.—A. Martin advises the application of a ligature of sterilized silk and then section of the cord with any form of a hot wire or similar device. Bleeding is thus permanently checked. The eschar is covered with antiseptic gauze and the cord dressed in the usual manner.

Nature's Methods of Protection against Infection.—By P. Baumgarten. A continued article.

Münchener medicinische Wochenschrift, Feb. 13, 1900.

The Application of Gelatin for Checking Cholæmic Hemorrhages after Operations on the Biliary System, besides Remarks on Poppert's Waterproof Drainage of the Gall Bladder.—Hans Kehr has had excellent results from the use of gelatin in several cases of cholæmic hemorrhage. The technique is very simple. Into 500 c.c. of a seven-per-cent. solution of sodium chloride he puts 10 gm. of white gelatin. The mixture is sterilized, and 200 c.c. at 38° C. is injected subcutaneously into the patient. He is positive that cystectomy combined with cysticotomy and drainage of the hepatic duct will prove superior to cystotomy with its numerous modifications, and also to waterproof drainage proposed by Poppert and two years previously by the author himself. This drainage consists in the insertion of a long rubber tube into the incised gall bladder, the tube being wrapped about with a great deal of gauze in order to protect the abdominal cavity from infection by the bile which has passed through the tube. The tube is snugly fastened into the incision by suturing the wound right up to the tube. This method is also applied to the drainage of the hepatic duct. Kehr believes that in order to obtain a permanent cure for the patient the surgeon, in the majority of cases, should not only drain or excise the gall bladder, but also lay great stress on the careful palpation and sounding of the bile ducts.

Critical Remarks on the Rosin Method for the Determination of the Reducing Power of Urine, etc.—L. Spiegel and G. Peritz criticise adversely the method devised by Rosin, which consists in pouring into an Erlenmeyer flask of 100 c.c. capacity 25 c.c. of urine diluted five times but still having a slight yellow tint. To the urine is added 1 c.c. of officinal caustic potash. Then liquid paraffin is poured over the mixture till three times its depth, and the whole is carefully heated almost to boiling. Care must be taken to exclude the air, and to hinder boiling, by means of which bubbles would rise to the surface and establish a communication with the outside air. Into the heated liquid there is poured through a burette whose tube is long enough to reach below the paraffin layer, 1 c.c. of methylene blue solution, 1:3,000, and the fluid is further heated over a wire net. After some seconds the blue color entirely disappears. Then by means of another burette there is added to the liquid, which is still being heated, but not boiled, sufficient 1:100 normal permanganate solution to cause the blue color to return, that is, till the fluid assumes a bluish-green shimmer.

A Contribution to the Etiology and Therapy of Episcleritis Periodica Fugax.—W. Stöltzing cites a case of this kind, and speaks later of the therapy and etiology of the affection. Fuchs says the therapy is for the most part without results, although quinine and sodium salicylate are the most effective. The author himself in the reported case has found potassium iodide to exert a very favorable influence. He also believes that there is no foundation for believing in a syphilitic etiology of the disease from the results of the iodide therapy, since all other symptoms of this affection fail, and since when the iodide is stopped the episcleritis always recurs soon. Syphilitic phenomena, if dispersed by potassium iodide so perfectly and quickly, are not accustomed to return in this manner.

Studies on the Inflammation of Serous Membranes.—R. Heinz states that his researches have led to the same results as those reached by Graser as well as those of some recent work done under Ziegler's direction. Endothelium prevents serous membranes from adhering together. Adhesion occurs when the endothelium is lost from any cause. This fact is not surprising. It is well known that when layers of uncovered connective tissue are laid together, they very soon grow together. In order that this may not happen, the serous cavities, the lymph spaces, the brain and spinal-cord cavities are covered with endothelium. Whenever the endothelium is destroyed by an injurious agent, the connective-tissue layers lying underneath adhere together.

On Intermittent Claudication.—Erb speaks of Grassmann's article on this subject in Ziemssen's *Festschrift*, in which the author gives an account of an interesting case observed by himself. Erb then calls attention to the fact that he himself, almost a year and a half ago, published a rather comprehensive article on the same subject in the *Deutsche Zeitschrift für Nervenheilkunde*, Band xiii. He makes this note in order that it may not be thought that no attention had been paid to this subject before the appearance of Grassmann's article.

On Total Stenosis of the Pylorus after Corrosion by Lye.—A. Hadenfeldt reports a case of this kind in a child six and three-quarter years old, and thinks that whenever corrosive poisons are swallowed, a stomach lesion should be thought of as well as the œsophageal trouble, and in case of intestinal disturbances that cannot be explained by the existence of the stricture of the œsophagus alone, stenosis of the pylorus should be considered. Relief should be afforded as soon as possible, to save the patient's strength.

An Improvement on the Intra-Uterine Dilating Sound of Doléris.—E. Toff describes his new instrument, which has the advantage of being separable into parts and so admits of being thoroughly cleaned and sterilized. Its arms are curved at a more obtuse angle than is the instrument of Doléris, which also is advantageous in its cleansing.

Epileptiform Attacks in Convalescence from Abdominal Typhoid.—F. Mühlig gives the history of a patient, a man aged twenty-three years. He speaks of the following points as noteworthy: the rapid succession of the attacks, the long duration of each, and the fact that the convulsions occurred only in one day and then never returned.

Hydrorrhœa Ovarialis Intermittens.—By Max Nassauer. A continued article.

Wiener klinische Wochenschrift, February 15, 1900.

On Malta Fever.—Alfred Brunner, in giving a careful description of this disease, says that according to Hughes the most striking characteristic of this disease is the long duration of the fever. Among three hundred and seventy-two cases, the fever lasted in the great majority from forty to seventy days, although Hughes had two cases in which the fever lasted over two years. The same author speaks of four principal types of the disease: (1) The malignant type, in which hyperpyrexia obtains, the temperature always rising above 41° C., and death following in a few days; (2) the indolent type; (3) the intermittent type; (4) the irregular type. Prognosis as to life is very good. As to the diagnosis, if the case presents absence of diarrhœa, a clear sensorium, absence of roseola and epistaxis, a moderate splenic tumor, and no or little headache, then it is easily differentiated from typhoid. It must also be diagnosticated from malaria. Serum diagnosis is valuable in this disease. The therapy of Malta fever is very limited. Symptomatic treatment is in order.

Landry's Paralysis with Especial Reference to its Bacteriology and Histology.—Julius Kapper carefully reviews a case of Landry's paralysis in which a bacteriological examination of urine and blood made in life, as well as the autopsy four hours after death, and the pathologico-histological examination of the central nervous system and peripheral nerves, gave a perfectly negative result. An auto-intoxication must be regarded as an etiological factor in this disease. This apparently originates in the intestine and would be accounted for by an increased putrefactive process. Thus would it be explained, if, on the one hand, in spite of apoplectiform clinical symptoms the post-mortem findings were negative, or, on the other hand, if we find pathologico-histologically a polyneuritis or myelitis which we regard as being of toxic origin. In the case cited, the presence of the products of intestinal putrefaction in the urine and the transitory improvement after copious alvine evacuation are in favor of the existence of an auto-intoxication. In view of this conception anti-fermentative measures would be indicated.

On Salivary Calculi.—Friedrich Hanszel notes three cases. The first calculus was caused by chronic inflammation of the glandular substance itself with consequent stagnation and inspissation of the secretion; it was not till later that this stone reached the duct through the salivary stream. The second calculus was caused by micro-organisms and was formed in Wharton's duct itself. The third was formed in Wharton's duct and resulted from the long-continued injury of the left sublingual by the mouthpiece of a tobacco pipe.

Vratch, January 29 and February 5, 1900.

Glioma of the Retina.—V. V. Zelenkovski reports a case of this affection in which he made a very careful histological study of the lesion, as a result of which he formulates the following conclusions: 1.

The cylindrical arrangement of a glioma is not fortuitous, but is very probably dependent upon the spherical shape of the retina and pressure exerted by the original cell-nests both upon the normal parts of the retina and one upon another. 2. Glioma of the retina may develop simultaneously from four layers—that of the nerve fibres, the ganglionic, the internal and the external granular. 3. Retinal glioma consists of spider cells with many offshoots, identical with the cells of the neuroglia and the spider cells of the retina and optic nerve, and of ganglion cells of various sizes in the midst of which are others resembling embryonal retinal cells. 4. The possibility of a glioma originating from the layers in which spider cells are ordinarily not encountered, and the presence of these embryonal nerve cells render very probable the view of Greef that a glioma of the retina is developed from neuroglic and ganglionic elements which may remain for a certain time quiescent in any layer of the retina and then take on growth when favorable conditions arise.

Transitory Spinal Paralysis.—L. R. Krever reports two cases of this affection occurring in apparently healthy women. There began quite suddenly, without any apparent cause, a paraplegia of the lower extremities accompanied with painless cramps of the legs, increased patellar reflexes, and disordered vesical and rectal functions. In one case sensation in all its forms disappeared and did not return for a long time, in the other it was preserved from the beginning to the end of the disease. There were no trophic disturbances, and all the severe symptoms disappeared as rapidly as they came on. From the first signs of the affection to complete recovery not more than two months elapsed.

The Origin of So-Called Acute Cataracts.—I. I. Maslennikoff reports a case of cataract occurring suddenly in a woman, twenty-seven years of age, of sound physical condition but suffering from an hysterical attack, and discusses the cases of sudden clouding of the crystalline during convulsions from other causes, a clouding attributed by some to spasm of the ocular muscles.

A Defence of Osteoplasty in Amputations.—S. I. Spasokukotski refers to a former article in which he advocated osteoplastic methods in amputation of the leg, as recommended also by Kocher, and returns to the subject in order to answer sundry objections which had been advanced against this procedure. He reports five cases of amputation illustrative of the advantages of osteoplasty.

The Value of Widal's Serum Diagnosis of Typhoid Fever.—Th. A. Dombrovski reviews at length the literature of this subject and reports several cases in which the test was applied, and concludes that it furnishes one of the most certain of all the evidences of typhoid fever, although it is not strictly pathognomonic.

A Nasal Speculum for Pediatric Practice.—J. I. Katz describes and pictures an instrument to facilitate inspection of the nasal passages in children.

The High Operation for Stone.—By V. I. Lisïavski. A continued article.

Endothelial Neoplasms of the Gastro-Enteric Tract.—By L. V. Soboleff. A continued article.

French Journals.

Milky Ascites with Leucocytes of Lymphatic Origin.—Fernand Widal and Prosper Merklen present the case of an alcoholic, aged fifty years, showing lactescent ascites. This is usually of chylous origin. It may exist without chyle, but the distinction presents great difficulties. A precise study of the leucocytes found in the fluid may show the lymphatic origin, as in the case presented, and give more valuable information than is furnished by the amount of fat present. —*La Presse Médicale*, February 24, 1900.

Botryomycosis.—Charles Lenormant describes a case of botryomycosis situated upon the dorsal surface of the right ring finger in a woman, aged thirty-one years, who had worked in straw in the family of a butcher. The raspberry-like appearance of the tumor, and possible indirect contact with animals, were sufficient for the diagnosis, which was confirmed by finding botryomyces in formative stages.—*Gazette hebdomadaire de Médecine et de Chirurgie*, February 21, 1900.

Observations on Cacodylic Medication.—Paul Dalché gives his personal results of treatment. He prefers pills of cacodylate of sodium, each containing 25 mgm. Various tabulated results are presented. He concludes that the drug is destined to render real service in tuberculosis when conditions of hygiene and therapeusis are favorable. He began with one pill at a dose and gradually increased to two and then three. —*Le Bulletin Médical*, February 24, 1900.

Tuberculous Stricture of the Small Intestine.—Th. Tuffier studies the hypertrophic form of stricture in tuberculous subjects. There are three varieties of stricture, the purely cicatricial, the primarily fibrous, and the hypertrophic. A case of the latter is given with illustrations. Surgical treatment has given thirty-seven operative cures out of forty-five cases.—*La Presse Médicale*, February 21, 1900.

Annals of Surgery, March, 1900.

A New Method of Suture in Operations for Inguinal and Other Forms of Hernia.—L. Freeman exposes the internal ring, ligates and cuts off the sac, which is knotted on itself. The cord being held out of the way, a loop of silkworm gut is passed from without inward through the muscular tissue on the umbilical side of the ring, then carried through Poupart's ligament from within outward. Another loop is similarly inserted near the pubic limits of the opening. A piece of stiff silvered wire long enough to reach the entire length of the inguinal canal is run through the loops, which are pulled tight enough to hold it in place. Another wire is laid along Poupart's ligament between the free ends of the loops, which are firmly tied over it, thus approximating the wires and bunching a quantity of muscular tissue against the ligament. The wires are bent upward at their pubic extremities so as to protrude through the external incision, thus facilitating their removal. The ends of the wires farthest from the pubes must be so placed that they leave the new internal ring neither too large nor too small. The cord is now dropped in place over the line of union, and the aponeurosis of the external oblique united above it, the upturned ends of the wires passing through the external ring. In uniting the skin, the free ends of the loops and the ends of the wires are brought out through the incision between the stitches. In from ten days to two weeks, which are long enough to procure reasonably firm union, the wires are removed by pulling on their protruding ends. This frees the loops, which are likewise readily extracted.

Fracture of the Neck of the Humerus with Dislocation of the Upper Fragment, with a Report of Three Cases Treated by Operation.—B. F. Curtis discusses the literature of this injury, and describes one personal case in which simple resection was done and two other cases in which he followed the method of reduction by open arthrectomy. He believes that when attempts at simple reduction under anæsthesia have failed, operative measures should be resorted to unless contraindicated by the patient's condition. Resection of the head of the bone should be reserved for those cases in which reduction is impossible or would extensively damage the parts. Resection will probably give a better result in fracture of the anatomical neck than of the surgical, but reduction is to be preferred in both. Motion should be begun as soon as the wound has healed.

A Case of Acute Osteomyelitis of the Femur with General Systemic Staphylococcus Aureus Infection, Terminating in Recovery.—A. A. Berg gives a detailed history of the case. Antistreptococcus serum was used, and there was an absence of any metastatic focus of infection. The organism was eliminated by the kidneys, causing acute degeneration of these organs as well as toxin poisoning of other viscera, but the patient finally recovered.

Prolapsus of the Rectum in Children.—C. G. Cumston states that in acute prolapse and invagination of the colon which are irreducible and at the same time present incarceration, gangrene, or intestinal obstruction, immediate resection should be done. Operation at a time of election should also be done in chronic cases which cannot in a reasonably short time be cured by milder therapeutic measures.

Effects of Intracerebral and Subcutaneous Administration of Tetanic Antitoxin in Tetanus, as Observed in Nine Cases.—R. Abbe narrates histories of two mild and seven severe cases. Of the seven seen this last summer, five were subjected to trephining. Three patients lived and two died. Good effects from the serum were noted in five of the nine cases, and four of the five patients recovered.

Report of a Case of Recovery after Gastrectomy for Carcinoma.—J. B. Harvie reports the case of a woman aged forty-six years, the stomach being resected and the œsophagus attached to the duodenum. The patient left the hospital in six weeks in good condition. A detailed report is given of the pathological condition found in the stomach.

Two Cases of Cicatricial Stricture of the Œsophagus Treated by Gastrostomy, the "String" Method, and Permanent Dilatation by Elastic Tubes.—B. F. Curtis reports the cases, one of a boy aged two and one of a girl aged nine years. H. prefers the method first described in 1894 by Stamm. The results in both cases were most satisfactory.

Report of Results Obtained in the Treatment of Ununited Fractures with the Parkhill Clamp.—A. L. Bennett reports nine cases of perfect union out of fourteen cases operated upon. The clamp was described in the *Annals of Surgery* for May, 1898.

Coccygeal Dermoid Fistula.—By R. T. Morris. See MEDICAL RECORD, vol. lvi., p. 531.

Treatment, February 8 and 23, 1900.

On Some Cardiac Affections due to Influenza.—J. L. Bunch has found as sequelæ of influenza increased frequency of cardiac rhythm, the "irritable heart" of Da Costa, the pulsus bigeminus, arrhythmia, and acute cardiac dilatation. Treatment must consist first of all in rest, absolute for a time, and then in the avoidance of any exertion which can throw a strain upon the heart. Later, carefully graded exercises may be used to assist the heart to return to its former condition of functional activity. A diminished intake and an increased output of fluid are recommended. Quinine and strychnine are usually of value.

On the Uses of the Stomach Tube.—Hampson Simpson would employ the stomach tube for diagnostic purposes; for the removal of the contents for clinical examination; for inflating the stomach, and for the detection of stricture at the cardiac orifice, for location and measuring, for transillumination, to ascertain the elasticity of the walls, to investigate the motor function, and with the *x*-rays to determine the size, form, and position of the stomach. As a therapeutic measure it is useful in cases of poisoning; for forced feeding, lavage, to apply electric treatment, for intragastric douching, for "internal massage," and for spasmodic stricture of the œsophagus.

A New Eyelid Forceps, with a Spring Lock that Can be Used on Both Sides.—O. Neustätter describes an instrument which he has found useful in practice.

Foreign Body, Chisel, Embedded in the Naso-Pharynx and Posterior Pharyngeal Wall.—By Cary B. Gamble, Jr., and L. M. Tiffany. See MEDICAL RECORD, vol. lvii., p. 67.

Locating Foreign Bodies in the Eye.—William M. Sweet reports the results of two years' work with the Roentgen rays.

Bulletin of the Johns Hopkins Hospital, February, 1900.

Report upon an Expedition Sent by the Johns Hopkins University to Investigate the Prevalent Diseases in the Philippines.—Simon Flexner and Lewellys F. Barker, in writing of this expedition, speak first of the value of their visit to Japan before proceeding to Manila. Here, they studied beri-beri, dysentery, and the bubonic plague. They first consider the diseases in the Philippines which affect the natives: (*a*) Skin diseases. Of the skin diseases prevailing among the natives, aside from smallpox and other specific exanthemata, are (1) diseases of the scalp, which are very frequent; (2) dhobie itch; (3) an affection probably identical with Aleppo boil. (*b*) Smallpox. (*c*) Leprosy; a definite focus of this disease exists in Luzon. (*d*) Tuberculosis; accurate statistics of this affection could not be obtained. (*e*) Venereal diseases; syphilis does not prevail unduly; chancroids and gonorrhœa are very common. (*f*) Beri-beri.

The chief causes of disability among American land forces are the enteric diseases: (*a*) Dysentery is responsible for the greatest amount of invalidation and the highest mortality. (*b*) Typhoid fever. (*c*) Malarial fevers. (*d*) Tuberculosis. (*e*) Dengue. (*f*) Tropical ulcers. (*g*) Wound infection. The writers conclude with a note on climatological and hygienic conditions existing in the islands.

A Case of Multiple Gangrene in Malarial Fever.—William Osler reports this rare and remarkable case. The patient, a man aged twenty-three years, was admitted to the Johns Hopkins Hospital in November, complaining of sores. Both hands, both feet, the left buttock, and the occiput showed gangrenous areas. Though the history did not suggest malaria, as in the routine examination of the abdomen the spleen was found to be considerably enlarged, the blood was examined, and very large numbers of æstivo-autumnal organisms were found. Large numbers of crescents were present. Cultures taken from the blood proved negative. The eosinophiles were only two per cent.

The patient was given quinine in full doses and began to improve rapidly. The larger sloughs were treated with linseed poultices made with bichloride solution.

Hæmophilia in the Negro.—Walter R. Steiner in reviewing this case states that in the literature only one well-defined case of hæmophilia is mentioned. This patient, a girl aged fourteen years, will consequently make the second on record. Treatment consisted in calcium chloride (gr. xv. t.i.d.) given in Wright's prescription. It is interesting to note that both the cases of hæmophilia were not in patients of pure negro blood. In the family of the second, contrary to the usual statement, both the males and the females seem to have been bleeders, but only one (a male) died from the effects of hemorrhages.

Benjamin Jesty: A Pre-Jennerian Vaccinator.—Thomas McCrae declares that there can be no doubt of Jesty having performed vaccination in 1774. The date of Jenner's first vaccination was 1796, although for many years before he had been making observations regarding it. Jesty was born at Yetminster in Dorset, and was a farmer.

Pediatrics, March 1, 1900.

Report on the Cause and Prevention of Infant Mortality.—Ernst Wende concludes his article, giving milk tests, adulterations, and grounds for condemnation of milk, with prosecution and penalties. He discusses preservatives of milk, condensation, etc., and concludes that the municipality should continue supervision upon the lines of: (1) Continuation of the license system; (2) milk should comply with State standards; (3) sanitary, non-absorbent milk-rooms should be constructed with reference to hygienic rules; (4) wagons should be protected from summer heat; (5) intercourse with houses containing contagious diseases should be prohibited; (6) obligatory cleaning of utensils should follow uniform method; (7) special supervision or abolishment of sale of milk in groceries, etc., is advised; (8) until State and city act in unison milk from unsatisfactory dairies should be interdicted or destroyed at the city line; (9) systematic reports should be mutually made.

Alcoholic Cirrhosis of the Liver in a Baby.—R. Abrahams gives the following case A girl sixteen months old had been ill for two months with greatly distended belly and general anæmic condition. The ascites interfered with walking. Diagnosis by exclusion. The baby had been accustomed to take beer, being allowed a glass a day from early infancy to improve nutrition. Paracentesis gave relief and permitted an enlarged and hard liver to be made out.

Rickets.—Charles Alling Tuttle presents a short paper. He finds the most plausible theory of causation is the so-called inflammatory theory, making the cause primarily a chronic inflammatory condition beginning in the bone-forming tissues. Under proper treatment the prognosis is good. Treatment is prophylactic, medicinal, mechanical, and operative.

Vaccination.—James W. Guest discusses the use of points versus glycerinized lymph, since the re-introduction of which a revolution, he says, has taken place in its favor. The quantity of lymph in the tube is too large for most people, especially children. The advantages are: Greater percentage in taking; it can be kept pure much longer, and one is more apt to get a pure article from the store.

The Thomas Knee Splint.—Henry L. Taylor says this is in effect an ischiatic crutch transmitting the weight of the body to the ground. An illustration shows its adaptability to stages of osteitis of the knee, ankle, and tarsus.

American Journal of the Medical Sciences, March, 1900.

Conclusions Based on Sixty Cases of Fatal Gastro-Intestinal Hemorrhage due to Cirrhosis of the Liver.—R. B. Preble states that fatal gastro-intestinal hemorrhage is an infrequent but not rare complication of cirrhosis of the liver. The cirrhosis is generally atrophic, although it may be hypertrophic. In one-third of the cases the hemorrhage is fatal; in the others, they continue at intervals for varying periods of time—even eleven years. In one-third of the cases, diagnosis can be made at or before the time of the first hemorrhage; in the others, only after months or years. Œsophageal varices are present in eighty per cent. of the cases, and in many of them are seen macroscopical ruptures. Fatal hemorrhages in cases showing no œsophageal varices are probably due to the simultaneous rupture of capillaries of the gastro-intestinal mucous membrane. In only six per cent. of the cases showing œsophageal varices was the cirrhosis typical.

A Case of Traumatic Varix of the Orbit in which Ligation of the Left Common Carotid Artery was Successfully Performed.—Charles A. Oliver reports this case of a man twenty-seven years old. The patient had received a crush of the head at four years of age, and this probably was the beginning of either an aneurismal varix between the petrous and the cavernous portions of the internal carotid artery and the corresponding cavernous sinus, or a varicose aneurism with an intervening sac between the two vascular channels. The situation was well protected in any case, and the growth very slow. A second blow on the same eye produced such painful symptoms that the patient presented himself for treatment. The left common carotid artery was tied. In five months the condition of an absolute secondary glaucoma was present. The fellow-eye continued normal.

The Histology and Histological Diagnosis of Adenomyomata of the Uterus.—John Cooke Hirst describes a case with this uterine tumor. In the uterus were found embryonal epithelial inclusions from the mucous membrane of Müller's duct. These were situated in the peripheral subserous layer of the myometrium. Adenomata with glands and cysts in scattered arrangement are to be considered as from the mucous membrane as soon as they are provided with cytogenic tissue sheaths around the glands. The formation of subserous adenomyomata from incorporated glands of the uterine mucous membrane is possible.

The Ehrlich Diazo Reaction.—James R. Arneill declares the results of his observations to confirm in most particulars the statements of Ehrlich. To be of value Erhlich's test must be made in accordance with his directions. The pink foam is an important factor. The statistics in cases in which the test has been correctly performed are overwhelmingly convincing as to the value of this reaction in the diagnosis and prognosis of typhoid fever, and the prognosis of diseases such as pneumonia, diphtheria, septicæmia, and especially tuberculosis.

A Case of Tricuspid and Mitral Stenosis with Adherent Pericardium.—T. L. Chadbourne describes this case. The patient was a woman thirty-six years of age when first seen in 1894. She was an epileptic.

The necropsy, held May 2, 1898, showed both the mitral and tricuspid orifices to be so narrow as to admit only the tip of the index finger. There was complete obliterating chronic pericarditis. The probability of a double mitral lesion was entertained from the first examination of the patient, but the true state of the case was not discovered till the post-mortem.

Gangrenous Dermatitis Complicating Typhoid Fever.—B. Franklin Stahl writes that bacteriological examination of this affection showed cultures of staphylococcus pyogenes albus and aureus, no other bacteria being found. In the reported cases, the trunk was the most frequent seat of the disease. Three of the ten cases resulted fatally.

A Critical Summary of the Literature on Retro-Peritoneal Sarcoma.—By J. Dutton Steele. See Medical Record, vol. lvii., p. 281.

The Practitioner, March, 1900.

The Pathology of Pneumonia and Pneumococcal Infections.—J. W. Washbourn says lobular pneumonia may be caused by several kinds of organisms; the most frequent are the pneumococcus, the streptococcus pyogenes, and the influenza bacillus. We should distinguish pneumonias by the cause and not by the anatomical effect, but imperfect methods make such classification impossible. Pneumococcal affections are here alone discussed. In lobar pneumonia the pneumococcus enters by inhalation. In severe cases they gain access to the circulation. Pneumonia is therefore a septicæmia, the lung inflammation being a local attempt to shut in the cocci from the circulation. In lobar pneumonia the cocci, probably by means of the lymphatics, pass through the whole of the lobe; in lobular they are localized to individual lobules. The discovery of large numbers of capsulated diplococci in the sputum is almost pathognomonic of pneumonia. More frequent bacteriological examination and classification of the different types of pneumococcal infections together will mark an advance.

The Treatment of Acute Pneumonia.—R. W. Philip says that the key is to be found in the recognition of pneumonia as a continued fever, and he prefers the name "pneumonic fever." The local lesions are analogous to the intestinal lesions of typhoid. The heart and circulation should be guarded. The diplococcus has yielded a rational basis for treatment, but the mortality has not yet been materially reduced. Attempts to destroy the organism have not been successful. Attempts to neutralize the toxic products are more promising. First of all, an abundant supply of fresh air and sunshine should be given and the strength husbanded. In most cases after the first two or three days alcohol will be useful. Cardiac tonics are called for when the circulation shows signs of embarrassment. Pain should be relieved quickly by poultices, fomentations, or morphine. Oxygen should not be ordered when the sick-chamber has become vitiated and stifling. Antipyretics are rarely needed. Open-air measures are to be adopted early in convalescence. Prophylaxis should follow the same lines as laid down for tuberculosis.

The So-Called "Ether Pneumonia."—J. Frederick W. Silk says the term is misleading and to some extent incorrect. There is no evidence that lobar or croupous pneumonia occurs after ether with greater frequency than might be expected from the normal rate of incidence of the disease. Other potent causes are at work, and it must be looked upon as a coincidence. Pneumonia after ether inhalation does not differ from the ordinary type. On the other hand, catarrhal pulmonary affections are prone to follow ether inhalations. Prophylaxis is important, and care should be exercised in administering ether to those with marked tendency to pulmonary complaints.

The Treatment of Pneumonia.—Julius Dreschfeld discusses croupous pneumonia in the adult. Weak and elderly persons should avoid the sick-room. The serum treatment is quoted from Washbourn. Older methods are reviewed. The object should be to enable the body to resist the toxic effects and to guard against threatening symptoms. We must guard from the onset against heart failure. If a diabetic develops pneumonia, the diabetic diet must be stopped and large doses of alkalies given. If a patient develops pleural effusion, one may wait till the pneumonia has subsided before paracentesis, unless there is much fluid or much dyspnœa.

Dust Pneumonia.—Alfred Hillier says that since pneumococci are constant in the sputum of normal individuals it is not improbable that the dust storms of sub-tropical countries may be capable of exciting inflammation, and act as a contributory cause, just as do exposure, alcoholism, trauma, etc. Osler speaks of chronic interstitial pneumonia due to the dust of certain occupations. Pneumococci may be inhaled with the dust.

The Diplococcus Pneumoniæ.—J. W. H. Eyre studies the morphology, biology, and pathogenesis of the diplococcus, with staining-methods, conditions of growth, action of germicides, media, vitality in cultures, resistant forms, rate of growth, pathogenic effects on animals, virulent types, post-mortem appearances, inoculation methods, etc. A table gives the susceptibility of animals.

Medicine, March, 1900.

The Operative Treatment of Fracture of the Patella; A Clinical Lecture Delivered October 20, 1899.—Charles Greene Cumston states that the first step in the operation for fracture of the patella is the opening of the joint and freeing the fragments of bone. There are various methods of making the cutaneous incision, certain conditions, however, being necessary for a proper incision. It should give plenty of space and freely expose the joint. The flap should be well supplied with blood at its base, and the latter should be broad in proportion to the flap's height. The cutaneous incision should be as far away as possible from the cicatrix in the bone in old fractures. He believes the proper course in case of a recently fractured patella is to wire it subcutaneously. Asepsis should be perfect.

The Nature of Neurasthenia: A Study of the Recent Literature.—Rosalie M. Ladova concludes from her researches on this subject that nerve exhaustion, fatigue, primarily a simple detention of reflex tonus, becomes only secondarily a chemical phenomenon — defective nutrition. Any purely mechanical stimulation of any of the peripheral nerves determines first increased tension of the general tone, an increase in energy, heightened intensity in the activity of all the organs, and later on augmentation in the combustion process. The nature of fatigue is primarily dynamic, and the primary source of vital energy is not in the nutrition, but in the centripetal nerve irritability.

The Intestinal Neuroses.—William J. Rothwell, after reviewing those neuroses which are functional disturbances, touches on their treatment. For peristaltic restlessness, in addition to general treatment, arsenic and methylene blue are especially valuable. In enterospasm sedatives and antispasmodics must take the place of purgatives; opium or codeine by the mouth; warm cataplasms on the abdomen, and soothing enemata at intervals. In obstinate cases, injections of warm oil are excellent. Enteralgia is amenable to treatment by anodynes.

A Laryngo-Hyoidectomy for Carcinoma, with the Report of a Case.—Jacob Frank states that the chief indication for complete or partial excision of the larynx has been carcinoma. In this case, which he reports, as soon as carcinoma was diagnosticated he advised laryngectomy. The patient was at date of writing—a few months after the operation—able to take solids and liquids by the mouth. The speech is intelligible, but a hoarse monotone. Recurrence is, however, likely.

A Case of Oculomotor Paresis following Indirect Violence.—C. A. Veasy reports the case of a man thirty years old. From the symptoms there was a paresis of the right oculomotor nerve following an injury to the left temple, and affecting those muscles supplied by the inferior division of the nerve to a greater extent than those supplied by the superior division, as some movement of the lid and of the superior rectus remained at the time of the first examination.

Prevention of Tuberculosis.—Charles J. Whalen believes the best means of prevention of tuberculosis to be the destruction of the sputum and the removal of those affected who are too poor to receive the necessary care at home to an isolation hospital which should be provided by the State.

A Case of Ulcerative Endocarditis, with Aneurism of a Sinus of Valsalva; and a Case Simulating Ulcerative Endocarditis.—By Augustus A. Eshner. See MEDICAL RECORD, vol. lvi., p. 525.

Deutsche Aerzte-Zeitung, February 15, 1900.

Vaporization of the Uterus.—H. Fuchs reviews the literature of the subject, giving Snegiureff the credit of being the first to show the hæmostatic effect of vaporization. Later this was applied to uterine hemorrhages, particularly those of the climacteric. The observations and methods of Pincus, Pawlik, Pet'ha, Baruch, von Weiss, Dührssen, and Flatau are related at length.

Upon the Disinfecting Power of Aluminum Acetate.—Aufrecht tabulates his experiments with the antiseptic properties of alsol, liquor Burow, and carbolic acid upon anthrax bacilli, streptococcus pyogenes, staphylococcus aureus, gonococci, tubercle and diphtheria bacilli. He concludes that the antiseptic effect of aluminum acetate is enhanced by the addition of tartaric acid.

Resorption of Medicines.—Gustav Wendt states that the method of administration with various drugs has a great influence upon their usefulness to the economy.

Upon the Occurrence of Inguinal Hernia.—By Graser. A continued article.

Zeit. fur klin. Med., Nos. 3 and 4, Vol. xxxix., 1900.

Observations upon Alimentary, "Spontaneous," and Diabetic Glycosuria, with Special Reference to the Carbohydrate Variations of Febrile and Alcoholic Patients.—J Strauss states that there is a difference between the alimentary glycosuria produced by the ingestion of sugars in predisposed individuals and the glycosuria due to the consumption of starchy foodstuffs. Numerous tables and many series of experimental cases are given upon the subject. He concludes that the alimentary glycosuria e saccharo is to be classified with the diabetic metabolic disturbances. The differences between the glycosuria e saccharo and ex amylo are apparently of a gradual nature. Disturbances of a mild character give rise, under otherwise favorable circumstances, to alimentary saccharine glycosuria, and disturbances of a severer nature diminish the tolerance for carbohydrates.

Chronic Articular Rheumatism and Arthritis Deformans in Childhood.—Axel Johannessen gives at great length the literature upon this subject from 1484 to the present time. Three instances are related with histories, photographs, treatment, macroscopical and microscopical examinations, etc. There are a number of excellent *x*-ray pictures. The first patient presented a chronic history, with pain and swelling in the ankle joint, and a good family history; atrophy set in later, then crepitation on movement. The second case gave a gouty family history, and the disease began acutely as in articular rheumatism; atrophy of muscles and bones occurred later. In the third instance the onset was chronic, atrophy was marked, and the joints were thickened.

Lymphæmia without Swelling of the Lymphatic Glands.—A. Pappenheim narrates an instance in which during an acute leukæmia the blood showed the ordinary typical lymphocytes in large numbers, although, as in all cases of chronic lymphæmia in contradistinction to lymphocytosis, large lymphocytes were not absent. In this case, the mild lymphatic enlargement could not be the primary source of the disease, but was rather the expression of the general infection. The second instance was a pure specimen of lymphæmia without lymphatic enlargements.

The Alkalinity of the Blood in Certain Pathological Conditions. — Burmin experimented with Tscherbakoff's modification of Landois' method of titration. The modification consists of dissolving the tartaric acid in a sulphate-of-sodium solution. The technique, with a tabulation of the various diseases, chronic gastritis, catarrhal icterus, cirrhosis, pneumonia, bronchial asthma, etc., and their results, are given.

Physiological Chemistry of Pentose and Methylpentose.—Suleiman Bey says that xylose and arabinose form lactose with the alkaline earthy oxides. Experiments are described showing the separation of pentose as barium dipentosate, and a new method of separating pentose from methyl pentose (rhamnose).

Determination of the Alkalinity of Small Amounts of Blood.—J. Hladik mentions a simple method of determining for clinical purposes the blood alkalinity. As little as 0.1 c.c. of blood may be used. Experiments with fourteen diseases are tabulated.

Analysis of the Irregular Pulse.—K. F. Wenckebach discusses allorhythmia, pulsus paradoxus, pulsus bigeminus, and pulsus alternans.

Finska Läkaresällskapets Handlingar, January, 1900.

Statistics of Venereal Diseases in Finland.—V. Leontjeff presents numerous statistical tables showing the prevalence of venereal diseases in Finland. The statistics are more accurate than they would be in most countries, for the people have an unusual dread of syphilis, and any one even suspected to have this disease is forced by the neighbors to undergo treatment or to secure a certificate of health from a physician. The writer states that syphilis is diminishing in that country and is also growing more benign, but the number of cases of gonorrhœa, on the other hand, is increasing.

Dystocia from Stricture of Bandl's Ring.—C. Hahl reports a case in a woman aged twenty-four years. The os admitted three fingers, but 10 cm. above this was an opening 2 cm. in diameter with thin edges but hard as if ossified. The opening was enlarged as much as possible by means of Tarnier's écarteur, and the fœtus was extracted after cephalotripsy. The woman recovered.

A Fifth Series of a Hundred Laparotomies.—G. Heinricius reports briefly on the fifth hundred laparotomies performed at the gynæcological clinic in Helsingfors. The mortality was four per cent.

Correspondence.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

The relief of Kimberley has been followed since my last communication by two events of the first importance in the progress of the war, the capitulation of Cronje's army and the relief of Ladysmith. Each event has enormous medical significance because of the strain that has been thrown thereby upon the hospital accommodation along all the lines of communication down to both bases, Durban and Cape Town.

The Physical Condition of the Boers, who capitulated at Paardeberg under Gen. Piet Cronje, after a struggle in which they displayed extraordinary resolution and gameness, was on the whole good, the number of sick and wounded being smaller than was expected. The total number of prisoners was just short of five thousand, forty-one hundred being taken in the bed of the Modder River, and six hundred (other accounts give eight hundred) being captured in odd parties during the many attempts to relieve the main force. Two hundred severely wounded were found in the Modder River laager, some of them being in a shocking condition for want of surgical aid. These were carried across the drift by the English bearers, and are by this time in one of the hospitals on the line of communication. At least two hundred more of the prisoners required medical attention, for during the last forty-eight hours of resistance Cronje's army was placed in sore straits. Their laager was in a terribly insanitary condition; dead horses and cattle in various states of decomposition were lying close to the tents, the food supply was mainly putrid, and the insecure shelter was made doubly trying by the cold, wet weather at night-time. There was practically no medical contingent with the force. The prisoners, when they reach the base, will be placed on board ship at Simmonstown—those of them, that is, who do not require hospital attention; and it is the experience of every one throughout this campaign that once a proper hygienic environment is provided health returns, so pure and clean is the air and so balmy the daily temperature.

The Base Hospitals Near Cape Town, *i.e.*, the three general hospitals at Wynberg and the sanitarium at Claremont, were becoming full again by the beginning of March, and it is fortunate that the previous lull in hostilities, due to the English having to wait for reinforcements, had emptied them before the stress of Lord Roberts' movements was felt in them. Sir Redvers Buller's second attempt to relieve Ladysmith, the march that culminated in the futile seizure of Spion Kop, cost the English one thousand and twenty in wounded, and five hundred of these, officers and men, were brought round from Durban to Cape Town by the hospital ships *Spartan* and *Lismore Castle;* but except for their patients and the sufferers from enteric fever contracted at the Modder River camp, the Cape Town hospitals were fairly empty by the time Roberts' casualties after the relief of Kimberley began to arrive. On the whole, the relief of Kimberley and the capture of Cronje's army did not cost the English many lives, but the list of casualties was a long one, and the Royal Army Medical Corps have to work at top pressure to keep level with what is required of them. Roberts had fifty thousand men with him when he entered the Orange Free State, and a large proportion of them were under fire for a week as well as making forced marches, so that it was well that the big base hospitals were ready to receive several hundreds of patients, and it was particularly well that all the arrangements for transport of the sick, which I have already described, were complete.

The Relief of Ladysmith was effected on the evening of Wednesday, February 28th, by Buller's force on the fourth attempt. No doubt the surrender of Cronje the day before had led to the withdrawal of some of the Boer troops, and possibly to the desertion of others, but enough remained to dispute with the English every foot of the way. The Dublin Fusileers and the Inniskillings, two Irish regiments, made some magnificent charges, and lost heavily, but when the relief was actually effected it was done without any severe casualties. But altogether, in his four attempts to join hands with Sir George White, Buller had some three thousand of his men wounded or too ill to fight. This means that an enormous strain has been thrown upon the hospitals in Natal. Even before the relief of Ladysmith this strain was shown by the fact that after the attack on Spion Kop a proportion of the wounded had been conveyed round from Durban to Cape Town. Since then there have been one week's continuous fighting and one week's desultory skirmishing, every day of which added to the total of wounded, while now the sick of Ladysmith have to be cared for. The succor of Ladysmith did not come one moment too soon. The rations of the beleaguered had been reduced to half a pound of meal a day, and the horses and mules were being used to supplement the meat supply. There were many cases of typhoid fever and many more of extreme weakness from emaciation. The whole of Sir George White's fine force, still numbering about nine thousand men, will require some days' rest and feeding before they will be able to assist in any forward movement, and the brigade of cavalry are rendered temporarily useless by the condition of their horses. Enormous preparations were fortunately made both at the fourth general hospital at Mooi River, the big hospital at Pietermaritzburg, the Durban hospitals, and in many private houses to receive the sick from Ladysmith whenever Buller should get there, so that the garrison, so long inactive, will soon be on the aggressive again.

Casualties in the Royal Army Medical Corps.—The deaths of two more officers of the R.A.M.C. are reported. Captain R. H. E. Holt, who entered the medical service of the army eight years ago, died of wounds received in one of the February engagements. Captain G. S. Walker, who was of the same seniority, died of typhoid fever in Ladysmith a week before the siege was raised. Lieutenant Mackenzie, who was wounded at Koodoosberg, having already distinguished himself at Magersfontein, had only joined the R.A.M.C. a few weeks before war broke out.

The Hospital Ship "Princess of Wales" arrived at Southampton, England, on February 25th, and on February 26th was visited by H. R. H. the Princess of Wales. The sick brought back expressed themselves grateful for a pleasant and uneventful passage. Most of them went to Netley Hospital on landing, where they and the other patients were visited by the Queen on the following day. Her Majesty brought to Netley the information of Cronje's surrender, which before her arrival was unknown to the men.

Lieutenant-Colonel Sloggett, R.A.M.C., and Mr. A. D. Fripp, respectively military superintendent and chief civil surgeon to the Imperial Yeomanry Hospital, arrived at Cape Town on February 28th. The Imperial Yeomanry Hospital is, I learn, to be placed at Deelfontein, a place some thirty miles south of De Aar Junction. Now that the English are sure of their lines of communication, the tendency there shown to establish hospitals rather nearer the fighting forces will be maintained, and the immensely long transports of the wounded avoided.

A Brave Medical Officer.—I send you a story of how an officer of the R.A.M.C. with Buller's force was wounded:

Captain ———, R.A.M.C., was wounded on January 23d near Colenso at a distance of one hundred yards while he was bending over in the act of dressing a wounded man. The wound of entrance was through the right rectus abdominis muscle, one inch below the costal margin and one and a half inches from the median line. The wound of exit was one inch above and one inch behind the centre of the right iliac crest. The symptoms were *nil* throughout, although it was difficult to suppose that the ascending colon escaped perforation. This officer watched himself carefully for symptoms which he believed must inevitably arise. He knew where the entrance wound was almost directly, but did not localize the position of the exit wound for two hours afterward. He tried to finish the dressing of the wounded man, but became giddy and had to lie down. He then remained perfectly still on his back for twelve hours, suffering much from the constrained position but nothing from his wound, and refused to take some water offered to him by the Boers. Two other men close by, who were also shot through the abdomen, did drink, although strongly advised by him not to do so, and soon began to suffer very much, one vomiting constantly. The captain had eaten only a little porridge for breakfast ten hours before, and took nothing by the mouth for forty-eight hours afterward. On the 31st he was convalescent, and he had no abdominal symptoms throughout.

The pluck which led a man in the agony of an abdominal wound to attempt completing his ministration upon another wounded man cannot be too highly commended. It will also be noted that the medical knowledge of Captain ——— probably saved his life; for had he moved much, or been made to vomit by drinking unwholesome water, the risks of peritonitis would have been incalculably increased.

THE CLIMATE OF NASSAU, N. P.

To the Editor of the Medical Record.

Sir: Nassau, the capital of the Bahamas, situated on the island of New Providence, has received of late very little notice, either in regard to the health-giving qualities of its wonderful climate or the opportunities one can enjoy for sport and recreation. I have been impressed more especially with the facility with which invalids recover from grippe and bronchial troubles, contracted in northern latitudes. Patients have come here suffering from colds and laryngitis, recovering from some of the more severe lung affections, like pneumonia, pleurisy, etc., and, after resting for a few days in rooms where the temperature is always from 70° to 73° F., their coughs leave them, the secretions are lessened, and they begin to enjoy sitting out of doors in the soft, balmy air, and, with proper precautions toward evening, gain rapidly in health and strength.

There is some humidity at all times, but clothes do not feel damp, and I have yet to see mould gather on boots or books, as it does at some of the Northern seaside resorts.

No rain falls through the winter months, and each day is a repetition of the one just passed—balmy breezes and cloud-flecked skies.

Tuberculous cases, either of lungs or larynx, and of an advanced type, do not seem to improve very rapidly, and I should not advise patients with the disease far advanced to come here. I consider it an ideal place for early nephritic disease; the skin is kept by gentle exercise in a moist condition, so helpful to impaired kidneys, and by care and a complete change of clothing on coming in from wheeling or golf, one avoids driving the blood back upon the internal organs, and obtains all the benefits of summer in home latitudes.

The changes of temperature are not sudden; the lowest point reached during my stay here thus far has been in January, when it was 62° F. at 6 A.M., and at that time New York was suffering from a cold storm and a temperature of 12° above zero. The usual daily range is from 70° to 73°, the highest having been 78.°

Judging from a visit here some years ago and my stay this winter, I feel no hesitancy in saying that Nassau combines all the qualities that go to make up an ideal resort for those who wish to escape the rigors of our northern winter, and also for convalescents who desire a climate which admits of constant out-of-door life. William E. Bullard, M.D.

Nassau, N. P., Bahamas, February 20, 1900.

CHLORAL AS A RELAXANT.

To the Editor of the Medical Record.

Sir: The treatment of strangulated hernia in your number of February 17th recalls some memories. While I believe in the operative treatment of hernia under favorable conditions, whether strangulated or not, there are times when it will be agreeable to patient and physician alike to avoid operation, if practicable. At such times chloral may be useful.

In the interior of Montana, twenty odd years ago, I was sole medical attendant with a detachment of troops in the field. A lieutenant of the line was ruptured. I failed to reduce the hernia by taxis under chloroform. I decided to try the effect of a large dose of chloral before undertaking operation with such assistance as the lieutenant's brother officers might render. I placed the officer on his back upon a cot, hips elevated, and gave as much chloral as I considered safe, and went about preparations for operation. Under the profound sleep induced the hernia was spontaneously reduced.

Many years later, at a remote frontier post, a civilian was brought to the hospital with a strangulated inguinal hernia. I failed to reduce it under chloroform, and proposed immediate operation. The patient begged for further time and trial. As night was approaching, and the symptoms were not yet alarming, I consented to postponement until the following morning. I treated the case in the same way as that of the lieutenant. I visited the patient before retiring for the night, and found him asleep in the position I had left him, and the hernia was reduced.

Having no failures to offset these cases, they seem to me suggestive.

S. S. Turner,
Acting Assistant Surgeon, U.S.A.

Chicago, March 8, 1900.

THE WORK DONE BY THE MARINE-HOSPITAL CORPS IN HAVANA.

To the Editor of the Medical Record.

Sir: A recent visit to Havana gave me the opportunity of inspecting the excellent sanitary work that is being done by Drs. Guitéras, Dudley, and their associate of the Marine-Hospital corps. These gentlemen deserve the greatest praise for their energetic methods and their efforts not only to check and uproot disease, but to protect the United States, and their ceaseless and successful labor is fully in accord with the spirit of reform inaugurated by the American authorities in the island of Cuba. Handicapped as they were and are by the criminal neglect of the Spaniards and the carelessness of the Cubans, they work with a rare will and intelligence that bid fair to reduce greatly the danger at our very doors that has menaced us for so long. The results already attained by this little body of medical men in a few months form a strong argument for placing every American port under the control of this branch of the national government, and will insure the uniform harmony of action which has become a necessity.

I may be pardoned for referring to the plan followed by the Marine-Hospital corps:

1. This branch of the service has the inspection of incoming vessels from foreign ports and from such home ports as are known to be infected. Two medical officers are assigned to this duty. The vessel enters the port flying the quarantine flag, and is immediately boarded by the medical officer, who makes a careful inspection of the ship, its crew, and passengers. The condition of the baggage is also carefully inspected, and if there has been or is a case of sickness of a contagious or infectious nature, the vessel is kept in quarantine at the Mariel quarantine station, ten miles distant. There the passengers are landed, and the vessel returns for disinfection of everything. Since the appearance of plague in Portugal and Spain, especially precautionary measures have been taken with the inspection of these vessels, and the entire crew and passengers pass through the hands of three different medical officers, who work independently of each other. Of course all of the necessary guards are placed on board to watch baggage and prevent people from leaving the vessel, or people from shore boarding the vessel.

2. Vessels leaving Havana for ports in the United States, or for other ports in Cuba, are invariably inspected by the medical officer in the same careful way, and he gives the vessel its necessary bill of health. It must be readily seen that in a harbor of this size, where the shipping commerce is so active, quite a large corps of medical officers is necessary, with quite a number of boats. There are at present five boats for the use of these officers.

3. The third department at this station is devoted exclusively to the inspection of passengers leaving here for the United States, and for certain ports in the island of Cuba. This inspection is carried out at this office by Dr. Menocal. A passenger going to any port in the United States is advised to present himself at this office for a certificate of health. He is examined for vaccination. If he has been successfully vaccinated and is in good health, a certificate is issued. If not, he or she is vaccinated and then allowed to proceed. In 1897 and 1898, when smallpox was widespread in the city, the officers were obliged to be much more exacting in regard to immunity to smallpox. Then a passenger was required to show recent and successful marks of vaccination. The vaccination marks that proved to be over four years old were considered insufficient, and at that time they vaccinated the passenger and held him for five days. He then presented himself at the local office, and if the operation was unsuccessful, he was revaccinated and then allowed to proceed. This year there has really been no smallpox, and it has been unnecessary to enforce so severe a regulation. The great value of the inspection of passengers by the service is manifest during the quarantine months from April 1st to November 1st. As is known, the different southern States have different regulations regarding non-immunes to yellow fever, and the Marine corps, while carrying out its own regulations, tries to co-operate with the various State boards of health. Passenger traffic between Havana and Florida demands the greatest vigilance on its part. During this quarantine period non-immunes to yellow fever are not allowed to go from Havana direct to Florida. The voyage from Havana to Florida ports is very short, and an individual who has been exposed to yellow fever could arrive in Florida two or three days before the completion of the period of incubation of the disease. Such passengers as are allowed to go are obliged to prove to us their immunity. A proof of having had a previous attack of the disease or proof to the effect that the individual has resided in an infected focus continuously for ten years is accepted. The greatest care has to be exercised in the consideration of various certificates of immunity presented by passengers. There is at the Havana office a record of thousands of names of people who are registered there as immunes to yellow fever. All baggage for the States is carefully inspected and disinfected by this service. Baggage for the southern States is disinfected on the barge *Protector*, and then sent on board the vessel. Baggage for ports north of the southern boundary line of Maryland is disinfected by the shore plant.

4. The disinfection of vessels for ports in the United States during quarantine period by the barge *Protector*, which is equipped with hot chamber, steam boilers, apparatus for bichloride spraying and formaldehyde disinfection. In the southern States disinfection and detention are required of all vessels. It has been possible to help the shipping interests a great deal, and time and a large outlay of money have been saved by disinfecting these vessels in Havana, when bound for southern ports in the United States. A vessel is disinfected by the *Protector*, and immediately on completion of disinfection, that is, after the sulphur has been in the hold for the required period, the vessel is given her bill of health and allowed to proceed, and she makes up her detention time on the voyage. A vessel going from Havana to a certain port can save one to three days' detention time. For instance, a vessel arriving at her destination three days out of Havana simply has to be detained two days at her port of arrival; whereas if she had gone directly to the port, and had been disinfected at the port of arrival, she would be detained five days after her disinfection.

5. Under this heading comes the inspection of cargoes (this is especially important during the quarantine period); character of cargoes inspected; method of packing; and certain prohibited material is of course not allowed.

6. Inspection of ballast. Vessels carrying ballast from Havana are required to carry either water ballast taken outside the harbor, or to carry rock ballast of a

hard and flinty character, which must be non-porous, so that disinfection can easily be carried out.

7. The inspection of all express matter, and the disinfection of such express packages as require it.

8. Under this heading comes the general sanitary supervision of the harbor; and the Marine-Hospital corps keep themselves informed as to the sanitary condition of vessels while in port, the different wharves, and, in fact, the entire bay.

9. Medical assistance given to American merchant vessels while in port. While this department has no hospital in Havana, the American masters invariably call on this service for medical assistance, and it has always furnished medical aid.

In addition to all this work it must be understood that there is a large amount of baggage to be handled during the year, and a regular baggage system has been established not unlike that of the railroads, with a baggage master, clerks, and checking system.

ALLAN McLANE HAMILTON, M.D.

Surgical Suggestions.

A Saponic Lubricant for catheters, etc.:

℞ White castile soap, powdered	℥ i.
Water	fl ℥ iij.
Mucilage of chondrus crispus	fl ℥ iij.
Formalin (forty per cent.)	♏ x.
Thymol	gr. v.
Oil of thyme	♏ v.
Alcohol	♏ xv.

Mode of preparation: Heat the soap and water, and stir until a homogeneous slime is formed; then add the three ounces of mucilage (made of the strength of one ounce of chondrus crispus to the pint of water). When cool, pour in the formalin, then the thymol and oil of thyme mixed with the alcohol; stir, strain, and keep in a covered vessel until all air bubbles have vanished. The result is an opalescent, slimy substance, of the consistence of honey, which should be put up at once in two-ounce collapsible tubes and sterilized.—GOULEY, *New York Medical Journal*, November 4th.

Hot Vapor as a Hæmostatic.—Among the disadvantages is the possibility of sloughing being produced. In parenchymatous bleeding the method is of surprising efficacy. Vapor under pressure has, however, little effect when the bleeding vessels have a decided calibre. Benefit is also secured from the asepsis and heat.—TECCHERELLI and BONFANTI.

Erosions of the Cervix Uteri.—It will be recognized from what I have said that I do not consider erosions the innocent or simple affairs which many I am sure do. I believe that they have a marked influence upon the nervous system of delicate women, and that something should be done for their relief. In order to attain better results than I can by applications, and in many cases by attention to the general health, I am more and more inclined to treat these cases by operation.—F. H. DAVENPORT, *Boston Medical and Surgical Journal*, October 12th.

Epistaxis.—If the bleeding is from far back and of a persistent character, plugging will be required. For this I use long strips of iodoform gauze which have been soaked in a mixture of peroxide of hydrogen and an antiseptic oil (containing menthol, eucalyptus, thymol, and camphor in liquid vaseline). The oil is somewhat hæmostatic, and prevents the gauze from sticking to the parts and setting up bleeding again when it is removed a day or so later. By putting the oil and peroxide in a small wineglass and soaking the gauze therein, the mixture is readily effected. To introduce take the nasal forceps and, carrying one end of the gauze far back, gradually fill the entire nostril. —GEORGE L. RICHARDS, *International Journal of Surgery*, October.

Hip-Joint Tuberculosis.—It is a rare thing nowadays to have a fatal septic arthritis follow resection, the former bugbear of the operation, the mortality having changed from sixty per cent. to less than three per cent.—MCARTHUR.

The treatment of hip disease is practically a purely mechanical problem; operative treatment is not demanded by more than one per cent. of cases that are subjected to even moderately effective mechanical treatment. We are of the opinion that operative treatment should be resorted to only as a life-saving measure, because the best results of operative treatment are inferior to the poorest results of mechanical treatment. —JOHN RIDLON.

Treatment of Fractures of the Patella.—Dr. Will H. Means (*Columbus Medical Journal*, July 5th) offers the following conclusions to an interesting article: (1) The results of the non-operative treatment are unsatisfactory both as to long confinement and functional disability. (2) The methods of maintaining apposition of the fragments by external appliances are unsatisfactory and unscientific. (3) In open arthrotomy the fragments can be carefully approximated and sutured in such a manner as will maintain apposition and, ultimately, bony union. (4) The operative method saves months of confinement, and gives permanent results. (5) The buried suture material should be absorbable, such as catgut or kangaroo tendon. (6) The field of operation should be continuously irrigated with a hot salt solution during the manipulation, and the incision closed without drainage. (7) The massage treatment begun at an early date is an important factor in restoring functional activity of the joint.

First-Aid Packages.—In a paper read by Dr. N. Senn at the American Surgical Association meeting held June 7, 1899, the following conclusions are formulated: (1) First-aid packages are indispensable on the battlefield in modern warfare. (2) The first-aid dressing must be sufficiently compact and light to be carried in the skirt of the uniform, or on the inner surface of the cartridge or sword belt, to be of no inconvenience to the soldier or in conflict with military regulations. (3) The Esmarch triangular bandage is of great value in the school of instruction, but in the first-aid package it is inferior to the gauze bandage. (4) The first-aid package must contain in a waxed aseptic envelope an antiseptic powder, such as borosalicylic powder, two sterilized safety pins wrapped in tinfoil, and between this package and the outside impermeable cover, two strips of adhesive plaster one inch wide and eight inches long. (5) The first-aid dressing must be applied as soon as possible after the receipt of the injury, a part of the field-service which can be safely entrusted to competent hospital-corps men. (6) The first-aid dressing, if employed behind the firing line, should be applied without removal of the clothing over the injured part and fastened to the surface of the skin with strips of rubber adhesive plaster, the bandage being applied over and not under the clothing. (7) The first-aid dressing must be dry and should remain so by dispensing with an impermeable cover over it, so as not to interfere with free evaporation of the wound-secretion. (8) The first-aid dressing should not be disturbed unnecessarily, but any defects should be corrected at the first dressing-station.

New Instruments.

A MIRROR-TEST FOR SIMULATED BLINDNESS.

By PERCY FRIDENBERG, M.D.,

ASSISTANT SURGEON, NEW YORK EYE AND EAR INFIRMARY, ETC.

One might paraphrase a well-known epigram to indicate that we are able to detect some frauds all of the time, and all frauds some of the time, but not all frauds all the time, and it is rather to supplement than to supplant the various methods for the determination of visual acuity in cases of alleged blindness that a new and simple apparatus is presented.

In a recent publication[1] the writer took occasion to point out that in almost all instances of simulation the claim of monocular amblyopia only is made, as this condition is so much more easily feigned than loss or deterioration of vision in both eyes. The great majority of detection tests aim to secure an admission of binocular vision or else to induce a physiological act inseparable from it, such as accommodation, convergence, or fixation; the former without the subject's knowledge, the latter independent of his will. The theoretical basis of such tests is that we are unaware of, or rather habitually overlook, the fact that we receive a double sensory impression from each object in our field of vision, which, falling on corresponding points of either retina, are translated by the cerebral centres into their real significance and are seen as one image.

The principle upon which the writer has proceeded is the corollary of this fact, for it is true, conversely, that when the image of an object falls on the retina of one eye only, as by reflection from a mirorr, we do not detect the absence of binocular vision, and fail to refer our sensory impression to its proper source so as to recognize which eye is being used. An instrument was devised to present the mirrored image of a test-card to the subject of examination in such a way that it can be seen by one eye only at a time, allowing a quantitative determination to be made of the vision of either eye without giving any clew as to which eye is being tested.

The test-cards are attached, one at each temple, to a spectacle frame in which, if necessary, glasses can be placed for the correction of ametropia, facing a small mirror which slides on a horizontal arm so as to allow its distance from the eye to be regulated. The mirror, which has a lateral adjustment to correspond with the inter-pupillary distance, is mounted on a short bar, hinging on the slide, and can be presented to either eye in succession by revolving the carrier through an arc of 180°. The lateral tilt of the mirror is indicated by a pointer on a horizontal scale. When the pointer is at 90° the mirror is at right angles to the line of vision of the corresponding eye, so that the latter sees its own reflected image. The test-card on this side, however, is not normal to the plane of the mirror, and its image is reflected only into the opposite eye, which the subject presumes to be unconcerned in the visual act, as this eye is nowhere in evidence. A slight tilting of the mirror to the temporal side, bringing the pointer to 95° or 100°, is sufficient to reverse the optical conditions, so that the test-card is approximately normal to the mirror, and its image is now reflected into the eye of the same side only.

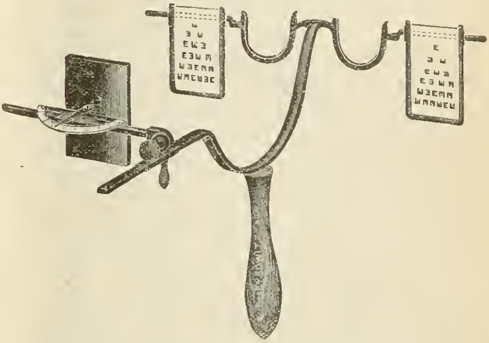
By switching the mirror-carrier over to the opposite side of the frame a similar double test can be applied to the other eye; or this can be accomplished without bringing the mirror over, by giving it a nasal tilt, bringing the pointer to 70° and to 60–65° respectively; so that in all eight variations can be rapidly obtained.

The following table indicates the various possible combinations:

Mirror before O. D.:
1. At 95 degrees right card is seen by right eye.
2. " 90 " " " " " " left "
3. " 70 " left " " " " right "
4. " 60 " " " " " " left "

Mirror before O.S.:
1. At 95 degrees left card is seen by left eye.
2. " 90 " " " " " " right "
3. " 70 " right " " " " left "
4. " 60 " " " " " " right "

In practice, the test is made with the mirror before the admittedly sound eye, but in the second position. If the card is read at this angle, it must be by calling into play the other eye which the malingerer does not even see, but whose action is demonstrated by having him close it. He will then be convinced, by seeing nothing, that the sound eye which he believed he was using was in no way concerned in vision. As a control test, the mirror is brought before the simulating eye, again in the second position, so that the card and this eye are seen by the subject, who naturally thinks that the mirrored eye is the one which receives the visual impression, whereas, in fact, it is seen by the sound eye which is nowhere visible. If it is now stated, as will most probably be the case, that the image cannot be seen, deliberate falsehood at least is made evident. The test is simple, rapid, and accurate, offers no clew to the simulant, and enables us to make a quantitative determination of vision. Another advantage lies in the fact that the instrument demonstrates itself and can be handed around to the members of a class, commission, or jury to prove the conditions found, without the necessity of going into any theoretical explanation of the optical principles involved.



Note.—As the mirror gives a reversed image, the characters must be printed backward, or face both ways, as A, O, V, Y, T, etc.; or the "illiterate" type is used. It should be remembered that the actual testing distance is twice the distance of the mirror from the eye. When the mirror is twelve inches off, the characters subtend a visual angle corresponding to a distance of twenty-four inches. The instrument may be used for distant vision by placing the patient with his back toward a test-card twenty feet away, and having him read in the mirror as before. For this test the apparatus should be firmly fastened to a suitable stand.

Periosteal flaps should be secured, if for no other reason, to prevent the disagreeable complication of skin-puckering in the stump.

---

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Fifty-third Meeting, Held Friday, February 2, 1900.

A. ALEXANDER SMITH, M.D., PRESIDENT, IN THE CHAIR.

A Case of Partial Laryngeal Paralysis.—This case was presented by DR. BEVERLEY ROBINSON. E. J. H——, male, twenty-nine years old, single, American, an electrician, came under observation November 24, 1899. He had tonsillitis three years ago, with a membranous exudate on the tonsils. His illness at that time was slight; he was not confined to his bed and was about in a few days. Hoarseness began four months later. During two and a half years it was not continuous. During a period of two months, for example, he had a good voice, and then, without apparent cause, he would lose his voice in about two months and regain it without obvious reason. Since last spring the patient had been continuously hoarse. During the past few weeks, occasionally and for a short time, the voice was much improved, but was never entirely natural. Until the patient came under Dr. Robinson's care he had had no general or local treatment. On October 31, 1899, he went to Saranac Lake. He stayed there one month, walking, skating, shooting, etc. His general health was good until last spring; since last spring he had been tired from overwork. He lost ten pounds in weight in six months. There were no fever, no cough, and very little sputa; no hemorrhage, no soreness of throat, no dysphagia, no dyspnœa. The patient was not nervous. He had had no syphilis. There was no localized swelling in the neck. On November 24, 1899, a physical examination of the chest showed doubtful signs of phthisis at the right apex. The larynx showed congestion and slight general infiltration. The right vocal cord moved well in phonation. The left vocal cord was covered by the epiglottis which inclined toward the right. No growth could be seen. The urine was normal. The blood examination showed a slight secondary anæmia, probably, which might, however, be a simple anæmia or chlorosis. Careful examination of the sputum on two occasions showed no tubercle bacilli. Treatment consisted of emulsion of cod-liver oil and creosote internally, with the use of a perforated zinc inhaler with creosote and alcohol. Local applications were made to the larynx of glycerite of borax and later of tincture of chloride of iron and glycerin, with a stimulating liniment to the neck. His present condition was as follows: The larynx showed very slight congestion in parts; the epiglottis was rather anæmic than otherwise; it had returned to the median line. The left vocal cord could now be seen. During phonation it approximated the median line, although sluggishly. The abduction of the left vocal cord was less active than the right. Physical examination of the chest showed little or nothing abnormal. The diagnosis at present was partial paralysis of the adductors and abductors of the left vocal cord. The causation was obscure. If it was a post-diphtheritic paralysis it should not be, probably, unilateral, and would not affect the abductor muscles of the larynx. If it was due to thoracic growth, without other signs, it should cause paralysis of the abductor muscles and not affect the adductor muscles. No doubt later a positive diagnosis as to causation might be made. The patient's general health was now thoroughly good.

The case reported might possibly be one of primary tuberculosis of the larynx, which was now in its incipient stage. The paralysis of the muscles on the left side might be explained rationally, in part by so-called functional disturbance, in part by tuberculous infiltration. If ulceration should occur bacilli might be found.

In connection with the above case, Dr. Robinson read the following letter from Dr. Frederic E. Sondern concerning the new culture method for the rapid growth of tubercle bacilli:

"Dr. W. Hesse published the method in the *Zeitschrift für Hygiene*, etc., in the fall of last year (1899). The essential element in the agar-agar culture medium is Nährstoff Heyden, an albuminoid product. The claims for the method are a rapid growth of tubercle bacilli in from five to six hours or more, and a retarded growth of many if not most of the contaminating bacteria contained in the specimens of sputum, etc., under examination. In this way he claims that a decided increase in the number of tubercle bacilli can be demonstrated when a specimen of tuberculous sputum is planted, which on usual microscopical examination shows but very few isolated bacilli. He records some failures when the sputum contains many contaminating organisms which at times overgrow the small colonies of tubercle bacilli in a very short time.

"For somewhat more than two months I have been applying the Hesse culture method to every specimen of sputum, urine, or other fluid sent to me for examination, which might possibly contain tubercle bacilli, and have for the present arrived at the following conclusions: (1) As yet the culture method has never revealed tubercle bacilli in specimens inwhich they could not be found by some other method of examination, excluding animal inoculation. (2) Not infrequently the rapid growth of contaminating bacteria ruined the culture attempt. This applies alike to sputum, urine, and other fluids. (3) Numerous specimens were encountered, however, especially of urine and tuberculous serous fluids, in which the usual examination revealed so few bacilli not always absolutely characteristic, while the Hesse culture method produced pictures justifying an undoubted diagnosis.

"Continued use of the method will demonstrate its practicability as well as its limitations much more firmly."

DR. J. W. BRANNAN asked Dr. Robinson if he had tried the tuberculin test.

DR. ROBINSON said he had not. He thought the suggestion a good one.

DR. BRANNAN said that his experience with paralysis of the vocal cords was principally confined to cases in which the disability followed intubation, and in which the tube had been left in for weeks or months. In those cases the paralysis was probably the result of pressure; the abductors were usually affected.

DR. F. P. KINNICUTT said he thought the tuberculin test would prove decisive, so far as the presence of tuberculosis was concerned. The occurrence of tuberculous laryngitis without previous implication of the lungs was exceedingly rare, and in such instances the lungs became involved sooner or later. Dr. Kinnicutt said that during the past ten years he had seen two or three cases in which the tuberculous process in the larynx preceded the lung trouble, so far as the absence of physical signs permitted one to judge; in two of the cases the laryngeal symptoms preceded the pulmonary symptoms by several months.

DR. ROBINSON, in reply to a question, said that no temperature elevation had ever been found. The man had lost about ten pounds in weight during the past six months.

DR. ANDREW H. SMITH, after an examination of the man's larynx, said he did not think the picture presented was one of laryngeal phthisis, although the general appearance of the patient, together with his loss of weight, pointed to a tuberculous trouble somewhere in the body.

Dr. Kinnicutt said it was entirely possible to have tuberculosis of the larynx without any elevation of temperature. The speaker said he had noted this fact even in cases in which the tuberculous process in the larynx was well advanced.

Dr. V. P. Gibney asked whether, in a case of tuberculosis of the larynx followed by pulmonary tuberculosis, the process extended by continuity or by general infection.

Dr. Kinnicutt thought that the most rational explanation was in an extension to the lungs through an inhalation infection.

Dr. T. Mitchell Prudden said he thought the explanation by Dr. Kinnicutt was probably the correct one. When these cases came to autopsy it was very difficult to make out how the infection had spread.

Dr. Gibney inquired whether the possibility of pulmonary infection could be averted by any surgical measures.

Dr. Kinnicutt replied that abroad a very radical method had been employed of scooping out these lesions in the larynx.

Dr. Robinson said that cases of primary laryngeal tuberculosis were so rare that the question of the mode of extension of the process to the lungs was still unsettled. In regard to treatment, tracheotomy had been tried in some cases, in order to help such a diseased larynx by putting it at rest. The method referred to by Dr. Kinnicutt, namely, scooping out the lesions, could not, in the speaker's opinion, be done thoroughly enough to bring about a cure. Personally, he relied upon local applications to relieve these patients. The most severe symptom of which they complained was pain on deglutition; this came on only after the epiglottis had become affected, and fortunately it was rare. After its onset, feeding was best accomplished through a nasal tube, into which the food could be introduced through a funnel.

Dr. Gibney said that in tuberculous foci in bones the tuberculous tissues had been found as far as one-quarter of an inch from the surface, and often very extensive excavations were necessary to eradicate the disease.

Exhibition of a Pair of Cystic Kidneys and a Cystic Liver.—These were shown by Dr. George L. Peabody, with the following history: The patient from whose body these kidneys were removed was a woman, forty-four years of age, a dressmaker by occupation. She entered the New York Hospital on December 26, 1899. She had had in early life scarlet fever, measles, and whooping-cough. Six years ago she had malaria. There was no history of other illness except that she had an attack of bronchitis two years ago. She used coffee and red wine in moderation, but no other form of alcohol. She said that she was easily fatigued all last summer, and that this sense of fatigue had gradually become a continuing condition of great weakness. There had been no headache or vertigo, and she had noticed no œdema. For several weeks past she had had cough and moderate dyspnœa. There had been no change in the quantity of her urine, but it had a bad odor, and she thought her kidneys were diseased. Her appetite was poor; her bowels were constipated, and her weakness was extreme. She was unable to stand. On admission to the hospital her respiration was 32; pulse, 106; temperature normal. She was fairly well nourished, but her color was bad. She presented a subicteric hue in her skin and conjunctivæ. Her tongue was dry, cracked, and coated. The apex beat of the heart was a little farther out than normal. The liver and spleen seemed both increased in size. There was a little œdema of both legs. Ophthalmoscopic examination revealed an absence of retinitis. She lived only a day and a half after entering the hospital. During that time her urine was twice examined. It was acid; specific gravity, 1.011; it contained from 0.75 to 1 gm. of albumin to the litre; no sugar; a thick sediment of pus, and no casts. She passed an average of twenty-two ounces a day. She was restless and very weak, unable to take other food than milk, of which she took between three and four pints a day. She died exhausted, in spite of active stimulation, early in the morning of December 28th.

The autopsy was made by Drs. G. P. Biggs and L. A. Conner, the pathologists to the hospital. The kidneys were both enlarged, weighing 468 and 472 gm. respectively. The kidneys preserved their usual shape, but owing to many projecting cysts they presented somewhat the appearance of bunches of grapes. On section both organs were seen to be composed of a multitude of cysts which varied in diameter from 1 mm. to 2.5 cm. These were most abundant in the peripheral parts. The usual topography of the kidneys was entirely lost, and in only a few places could anything resembling kidney tissue be recognized by the naked eye. Several of the larger cyst cavities contained thick, grumous pus. Some contained thick, brown, gelatinous material, which was coagulated by formalin six per cent. Some contained grayish-white, thin translucent material, which was not much changed by formalin. The pelves were small and somewhat compressed by cystic kidney tissue. The ureters and blood-vessels were normal. The liver showed numerous cysts varying in size from 2 mm. to 1 cm. These were seen on the surface and deep in the liver tissue. The weight of the liver was 1,770 gm. The heart showed slight hypertrophy of both ventricles. The lungs showed emphysema. Microscopical examination showed many microscopic cysts in the cortex and medulla of the kidneys, and very advanced interstitial changes with numerous microscopic abscesses. The small cysts in the sections were all lined by epithelium of the tubes, which had undergone a varying amount of change. Numerous microscopic cysts were seen in liver sections, all lined by epithelium of the gall ducts, which had also undergone a varying amount of change in form. The liver also contained microscopic abscesses; but in general its structure was not abnormal.

Dr. Peabody called attention to the fact of the possibility of a woman attaining middle life with a fair degree of health in spite of the fact that her kidneys must have been congenitally cystic to an extent probably unusual.

Dr. Prudden said that a similar lesion in the human kidney and in the kidney of the pig had been shown at the New York Pathological Society some years ago. The condition of the liver in the case reported by Dr. Peabody was certainly a rare one, and was especially interesting in its association with the kidney lesion.

Dr. Andrew H. Smith inquired what the woman's condition of health had been earlier in life.

Dr. Peabody replied that she had had all the diseases of childhood—scarlet fever, measles, etc. Six years ago she had malaria and two years ago bronchitis. During the summer preceding her death she was easily fatigued, and this symptom grew more pronounced in the autumn and winter.

Dr. Smith asked whether such a condition of good health in early life would be consistent with the idea that the condition of the liver and kidneys was congenital.

Dr. Peabody, in reply to Dr. Smith, said the microscope showed that in spite of the extensive degeneration there was still a good deal of kidney tissue left which was able to functionate, and this was proved by the fact that she passed considerable quantities of urine. The theory was that this condition of cystic degeneration was present at birth and increased as time went on.

Dr. Prudden said he thought such a condition of the kidneys might exist in spite of the absence of symptoms.

Dr. Brannan asked Dr. Peabody whether he regarded the presence of these degenerative conditions in the liver as well as the kidneys as associated with one another, or merely accidental.

Dr. Peabody replied that to him the condition was quite an unusual one. Certain degrees of cystic degeneration of the kidney were quite common, but he had never before seen the liver similarly affected. Probably in the case he had reported the condition of the liver and kidneys was dependent upon the same unknown cause.

Some Lines of Progress and Drift in Pathology.—This paper was read by Dr. T. Mitchell Prudden (see p. 397).

Dr. Brannan said the general practitioners of the present day appreciated very much what the pathologists were doing for them in clinical microscopy. That branch of medical science had advanced to such a degree that men who were engaged in general work could hardly keep pace with it.

Dr. Charles McBurney said he had been extremely interested in listening to Dr. Prudden's paper, which contained a *résumé* of what had recently been achieved in the field of pathology. The agreeable manner in which the scientific facts were set forth did not detract from their interest, and the speaker expressed the hope that Dr. Prudden would some day find the time to elaborate further many of the points which he had merely touched upon in his paper.

Dr. Robinson said that in view of the rapid strides made in pathology and chemical analysis during recent years, it was hardly possible for a man who was engaged at clinical work to become sufficiently expert in the use of the microscope, the various staining-fluids, etc., so that he could rely solely upon his own opinion in the diagnosis of an important case in which such examinations were necessary. The speaker said he thought that in cases in which a microscopical examination was deemed important, the aid of a skilled pathologist should be called in, and in all hospitals this work should be delegated to a competent man.

Dr. Andrew H. Smith said he had greatly enjoyed the poetic flow of Dr. Prudden's words. To follow in the same strain, the speaker said that, in his opinion, the "chalkiest" of all the "chalk eggs" upon which pathology was "brooding" was the conception of an intermediate process between the noxa and its action upon the tissues, a process termed "inflammation." The speaker said that whenever he found an egg on which a name was pencilled ending in "itis" he was inclined to look upon it as "chalk," and to throw it out of the nest. It seemed to him that the cause which produced disease grappled directly with the tissues, and not through a more or less imaginary process called inflammation. Conditions which were utterly different had been forced into seeming relationship by including them under this common designation, as, for example, keratitis and peritonitis. It was time that we addressed ourselves to the study of the morbific agent on the one hand and the reparative process on the other, without mixing them up with a hypothetical *tertium quid*, which was only a sickly survival of what was rapidly becoming obsolete.

A Case of Trichinosis in which the Diagnosis was Suggested by Examination of the Blood.—This case was reported by Dr. F. P. Kinnicutt, and confirmed by the discovery of the parasite in the muscle.

Dr. Brannan asked if the fæces were examined.

Dr. Kinnicutt replied that they were not; that it was not considered necessary, as the diagnosis was confirmed on the day following the patient's admission to hospital. The patient was an American. He had been in the habit of eating pork, always cooked, two or three times weekly. Dr. Kinnicutt said it had been shown that living trichinæ might exist in partially cooked pork; it was not necessary that it should be raw. In reply to a question by Dr. McBurney, as to what finally became of the trichinæ in the tissues, Dr. Kinnicutt said that they became encapsulated and gave rise to no further trouble. A man might enjoy very good health, in spite of the fact that his muscles contained many of these encapsulated parasites.

Dr. Peabody said he had seen these parasites in the muscles in the course of dissection.

Dr. W. Gilman Thompson said the case reported by Dr. Kinnicutt emphasized the value of a differential blood-count at the bedside as an aid to diagnosis. This subject was still in its infancy, but from the present outlook much might be expected from it in the future. The mere existence of a leucocytosis might be sometimes misleading, but a careful blood-count, although a very laborious process, certainly ought to be made in cases of this nature. Dr. Thompson said that another interesting point was the relation of cause and effect. Why should the eosinophilic cells be so increased by this irritant in the system, and should the production of these cells be regarded as a pathological process? The speaker said he was under the impression that the eosinophiles were also increased in the presence of certain other intestinal parasites.

Dr. Kinnicutt said that an increase in the eosinophilic cells had been noted in various pathological conditions. Chief among these were bronchial asthma, spleno-myelogenous leukæmia, and certain affections of the skin, pemphigus, psoriasis, prurigo, and chronic eczema. Concerning the nature of the eosinophilic granules and the origin of the cells containing them, varied views were held. The view most generally held was that they were developed from the polymorphonuclear neutrophiles by a kind of ripening process. Brown was led to believe, from his study of cases of trichinosis, that the transformation occurred in the muscles.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 1, 1900.

William H. Thomson, M.D., President.

The discussion on cancer, begun at the last meeting was continued at the present one.

Cancer of the Larynx.—Dr. D. Bryson Delavan took up the consideration of this topic. He said that the most common, as well as the most dangerous, form of cancer of the larynx was epithelioma. The consideration of the surgical management of carcinoma would include all that could be said about the radical treatment of excision of the larynx in general. The responsibility of determining the possible malignity of a given case might fall upon any practitioner, and hence the great importance of this subject. During the past ten years much attention had been devoted to laryngeal carcinoma, though it must be confessed that little progress had resulted, except as to its surgical treatment. Thus far no successful system of toxic treatment had been suggested for carcinoma of the larynx. The attempted cure of these cases by endolaryngeal methods had been practically conceded to be a failure, notwithstanding the few comparatively successful cases of Fraenkel and others to the contrary. No one should attempt the radical operation for laryngeal cancer until one had thoroughly mastered the subject.

Diagnosis.—The beginnings of intra-laryngeal carcinoma were usually too trifling to attract attention. A small area of infiltration first developed, and this might become diffuse, or more commonly the site of a small outgrowth, often papillomatous in appearance. Soon, too, highly suggestive signs were liable to present themselves, viz., (1) sudden, sharp pain, and (2) distinct loss of motion on the affected side of the larynx. The pain was distinct from that observed in other affections of the larynx, or in ordinary sore throat. The loss of motion of the affected side was due to infiltration of the muscles controlling the arytenoid cartilages. In a doubtful case care should be taken at once to exclude tuberculosis by exhaustive examinations of the lungs and of the patient's sputa, and syphilis should be excluded by the therapeutic test. It had been generally recommended that as soon as the growth became sufficiently developed to admit of a fragment being removed, this should be done, and the diagnosis established by microscopical examination; but instances innumerable were on record in which, with every sign of malignity clinically, the result of the microscopical examination had been negative, or directly misleading. A notable example of this was the result of Virchow's examination in the case of the late Emperor Frederick. If there was one principle which had long been established with regard to epithelioma, it was that irritation of such a tumor tended to accelerate its growth, and was, therefore, directly harmful. This was particularly true of epithelioma of the larynx, and hence the wisdom of not being too eager to remove a fragment of a suspected growth for microscopical examination. One could rely fairly on three signs, viz., (1) continued hoarseness without other obvious cause; (2) a characteristically sharp and sudden pain, and (3) loss of motion on the affected side. Removal of a fragment of the growth was difficult of accomplishment, and was painful and harmful to the patient.

Treatment.—While a fair number of cases of extirpation of the larynx had resulted in prolonging life in comparative comfort, it was universally conceded that the best results had been obtained in cases in which an early diagnosis had allowed of the removal of a moderate portion of the larynx, and, at the same time, total excision of the disease.

Dr. Delavan then presented a gentleman upon whom Dr. Curtis had successfully operated some time previously.

Dr. B. Farquhar Curtis said that this man had been operated upon by him three years ago next June. The packing had been removed very soon after operation, and the patient had been allowed to swallow within twenty-four hours, this having been accomplished by placing him in such a position that his head hung far back. His voice had begun to return about one year ago, and was now fairly good.

Cancer of the Gastro-Intestinal Tract; Diagnosis and Treatment.—Dr. B. Farquhar Curtis read this paper which will appear in a future issue.

Cancer of the Stomach.—He said that some recent statistics showed that over twenty per cent. of all cancers occurred in the stomach. Among men suffering from cancer, nearly one-third had cancer of the stomach; in women, only about thirteen per cent. were similarly affected. In 1896 a large number of cases of operations on the stomach by expert German surgeons had been collected, and the mortality from one hundred and seventy-three of these had been thirty-one per cent., as against seventy to eighty per cent. at the time when the operation had been first introduced. Three of the cases had been followed for four years, and had been well up to that time; four cases had remained well for over five years, and at least three cases had remained well for eight years. This showed the ability of the operation to cure cancer radically. About two-thirds of the cases could be carried through the severe operations with success. The reduction in mortality was partly due to the improvement in technique, and partly to the earlier diagnosis of these cases. The chief gain in the future would probably arise from the diagnosis being made still earlier. This same factor should increase the number of cures. All cases of cancer could be divided into two classes—(1) cases with a perceptible tumor, and (2) cases without any perceptible tumor. Quite a number of cases of cancer of the stomach came to the surgeon simply with a tumor, and with an entire absence of all symptoms. Not uncommonly the tumor was detected accidentally. The points of importance to the surgeon were the size of the tumor, its mobility, its location, and the previous history. The very large tumors had been formerly considered to be inoperable, but as patients had survived two years or more after the extirpation of these large tumors, this opinion could no longer be held. The location of the tumor was usually at the pylorus, though it might be farther to the left. There were some cases on record in which a supposed tumor of the cæcum had proved to be a tumor of the pylorus displaced in that direction. It was quite important in making the diagnosis in these cases to exclude gall stones. Probably the majority of patients presented themselves either with a tumor which was adherent under the liver or ribs, so that it was practically concealed, or with a very small tumor. The symptoms formerly laid down—vomiting, hæmatemesis, and pain—should be set aside as of no value in making the diagnosis of cancer. Perceptible distention of the stomach was not very common in malignant disease; hence a true dilatation of the stomach would be a point in favor of a benign stenosis of the pylorus.

Chemical Diagnostic Tests.—The chemical examination of the stomach contents had become the modern means of making the diagnosis. Authorities were not yet agreed concerning the value of some of these points, and yet, in most cases, reliance must be placed on them. The first thing was to give a test-meal, and determine the presence or absence of hydrochloric acid. About all that could be said about the absence of hydrochloric acid from the stomach was that it raised suspicions of the presence of cancer. The presence of lactic acid had also been noted, and it had been maintained by some observers as absolutely diagnostic of cancer of the stomach. An important element in this diagnostic study was the digestion of albumin. Owing to the great atrophy of the gastric glands in these cases the digestion of albumin was usually quite defective. The study of the motor insufficiency of the stomach was also of significance. In most cases there was great motor insufficiency of the stomach, this organ not emptying itself even though there was no stenosis of the pylorus, and the cancer was situated on the anterior or posterior wall. It should be remembered that hyperacidity of the gastric juice was the rule in cases of benign stenosis of the pylorus. If there was no stenosis and the hydrochloric acid was diminished it would be necessary to study the motility of the stomach. The advantages of studying the washings from the stomach had been emphasized by many physicians. Microscopical examination of the stomach contents included a search for a certain bacillus resembling a baseball-bat in appearance. This organism probably belonged to the fermentation forms, and was said to be a positive sign of the presence of cancer of the stomach. Hemmeter maintained that it was proper to operate in a case in which there were rapid emaciation, absence of hydrochloric acid, presence of lactic acid, reduction of albumin digestion, and the presence of the bacillus just mentioned, even in the absence of tumor, provided no benefit followed appropriate medical treatment for a period of several weeks.

Indications for Operation.—The first indication for operation, Dr. Curtis said, was the presence of a tumor. The second indication would be obstinate vomiting. A third would be a dilated stomach. In nine-tenths of the cases the dilatation would be the result of stenosis of the pylorus, and in the remaining ones it would be due to enteroptosis. He was inclined to think the repeated vomiting of blood should be considered as an indication for operative intervention. Severe and frequently recurring pain in the stomach, resisting lavage and appropriate diet, would seem to warrant an exploratory incision, although doubtless some of these cases were dependent upon a neurosis. Even here, however, the operation had been known to effect a cure. At the present day, the surgeon was able to say not merely that an exploratory operation would do no harm, but that it would probably do good, even in the event of there being no malignant disease present.

Gastric Ulcer Predisposes to Cancer.—Dr. Curtis said that he believed there was very considerable danger of gastric ulcers being converted into cancer. A very large number of cases of carcinoma of the stomach gave a history of prolonged stomach difficulty, probably dependent upon ulcer.

Selection of the Operation.—It was not true, at the present time, that a tumor should not be removed simply because of its large size; nor should adhesions limit the operation, because these adhesions were often inflammatory, and portions of organs involved in these adhesions had often been removed successfully. A fairly long survival had been known to follow the removal of glands found to be cancerous at the time of their extirpation. Of course, very large and extensive involvement of the glands contraindicated the removal of the tumor, but here a gastro-enterostomy could be done. It should not be attempted, however, unless there was decided stenosis. Gastro-enterostomy, done for the relief of the pain of carcinoma of the stomach, was an illusion, as it only cleaned the stomach and supplied proper drainage, whereas the pain was really due to involvement of the retroperitoneal glands. The longest survival after gastro-enterostomy recorded had been two years and a quarter; the average time was less than six months. This operation was capable, however, of giving very marked relief from the distressing vomiting when stenosis was present.

Intestinal Carcinoma.—The speaker said that carcinoma of the intestine was generally annular in form and spread very slowly. Both of these facts could be explained by the arrangement of the lymphatics in the bowel.

Arrangement of the Lymphatics.—The lymphatics were in two groups, submucous and subserous. These two systems did not connect, but both passed through the lymphatic glands at the mesenteric attachment, and then passed into the second tier of these glands—the ones usually spoken of as the mesenteric glands. The lymphatics next passed into the retroperitoneal glands. In this way the body was protected by three lines of defences. From these considerations it followed that even after carcinoma had lasted for years and a tumor of considerable size had been formed, there was a chance for a cure. A specimen was exhibited showing very beautifully this arrangement of the lymphatic glands.

Pathology.—Carcinoma of the intestine usually began its growth in the mucous membrane, and spread circularly around the bowel. As soon as this had occurred, fibrous tissue began to form at the base, and then contracting, choked off the blood supply, and led to the formation of an ulcer in the centre. On the edges the process spread slowly, but not along the line of the lymphatics. This resulted in a stricture, which, although in reality fibrous, had its origin in carcinoma. The tendency to produce metastases or glandular invasion was very slow, so that the process might go on for years without giving any symptoms except those merely the result of mechanical obstruction of the bowel. In these cases often no special difficulty was experienced until a seed or other substance suddenly blocked up the already narrowed lumen of the bowel, thus giving rise to what appeared to be an attack of acute intestinal obstruction.

Symptoms.—These patients were usually constipated, and suffered at times from attacks of subacute intestinal obstruction. Sometimes there would be "ribbon stools" or pill-like stools, like the discharges from the bowel of a goat.

Prognosis.—In eighteen cases at Czerny's clinic the mortality from operation had been fifty per cent. Of the recoveries, one patient had remained well for ten years; four were known to have remained well for periods varying from one to three years and a half after operation. The mortality was high because many of the cases had been operated upon during the period of acute obstruction, and also because, in some instances, tumors had been very large, necessitating very severe and prolonged operations.

Treatment.—The palliative operations were colostomy and anastomosis. The latter consisted in making a communication between the bowel above and below the stricture, leaving the tumor in place. It was, however, a most useful operation in suitable cases because it established, so to speak, an internal anus. The operation of "exclusion" of the intestine had been lately introduced. This consisted in uniting the ends of the healthy bowel, and closing one end of the loop in which the tumor existed and opening the other upon the skin. This admitted of the discharge of the contents later on without causing any obstruction. Colostomy was of the greatest value when the cancer had caused obstruction. He favored resort to this operation earlier than was commonly done.

Treatment of Inoperable Cancerous Tumors.—DR. WILLIAM B. COLEY read this paper. He said that during the last few years several methods of treatment for inoperable cancer had been advocated. He had tried the method of administering thyroid extract in a few cases, but with negative results. The treatment by injections of alcohol gave little chance of success. The same was true, he thought, of cataphoresis. The results of his treatment by the use of the mixed toxins of erysipelas and of the bacillus prodigiosus still continued to be satisfactory. He preferred to make use of the mixed unfiltered toxins made from cultures in the same medium, and sterilized by heat. The injections should be made directly into the tumor whenever possible. The initial dose should be rarely more than half a minim. When the injections were given at a point remote from the tumor much larger doses could be tolerated. If no improvement was observed after three or four weeks of this treatment it was seldom advantageous to continue it. If improvement occurred, the use of the toxins should be persisted in until the tumor had entirely disappeared, or until it was evident that the toxins had lost their controlling influence. The question of harm from long-continued injections was a very important one. It had been proved that moderate doses could be administered twice a week for a period of two years and a half without doing harm. In another of his cases the treatment had been continued for four years, and the patient, a physician, was now in perfect health, at the end of six years from beginning the treatment. The action of the toxins, he thought, could be explained only on the parasitic theory of the origin of cancer. In the majority of his cases both the clinical and the microscopical diagnosis had been confirmed by expert pathologists and clinicians.

Results.—Of the total number of cases treated, eighty-four were round-celled sarcoma, twenty-one spindle-celled, and nine melanotic sarcoma. Of the round-celled variety forty, or less than half, showed more or less improvement, and in three the treatment had been successful. On the other hand, of the twenty-one spindle-celled sarcomata, ten had disappeared entirely, and all of the remainder had shown marked improvement.

Risks.—He believed that under proper precautions the risk from this treatment was very slight. He had employed it in upward of two hundred and thirty cases, with only two deaths, and these latter had occurred about four years ago. It should not be forgotten that this method was recommended only for inoperable cases. He recommended that it be used as an adjunct to operative measures, the toxins being administered immediately after operation instead of waiting for a recurrence.

Dr. R. H. M. Sell referred to a case which had come under his care in 1873. Eighteen other physicians had seen this case, and all of them had made a diagnosis of cancer of the stomach, but to this he had taken exception. The patient had been almost exsanguinated at the time. The post-mortem had revealed the presence of cicatrices and fresh ulcerations in the œsophagus, and the same condition in the duodenum.

Dr. Thomas H. Manley asked Dr. Delavan if it was not true that life was as much prolonged and as much relief was afforded by tracheotomy alone as by the removal of a part or all of the larynx in carcinoma of this organ. He also called attention to the frequency with which hæmatemesis in young persons was due to gastric ulcer, and maintained that tumors in the posterior wall of the stomach near the cardiac end were absolutely inoperable.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 26, 1900.

George B. Fowler, M.D., President.

The Physiological Properties of the Suprarenal Extract.—Dr. B. Moore, professor of physiology at Yale, discussed the physiological properties of the suprarenal extract. He said that Addison, by most painstaking post-mortem examinations of the suprarenal gland, had found that, in the disease bearing his name, there were certain constant changes in this gland. He found nervous and muscular changes associated with a very low blood pressure. This lowering of the blood pressure was all the more remarkable when viewed in connection with experiments on injecting the suprarenal extract into animals. In 1855, Brown-Séquard had begun a series of experiments on the removal of one or both glands in animals. He found that the removal of one gland often proved fatal, and that the extirpation of both glands was rapidly followed by death in every instance. These results had been very much disputed, and his experiments had been repeated by dozens of experimenters. Schaffer had suggested that the cases in which other experimenters had not observed death after the removal of both suprarenal glands could be explained by supposing that there had been present accessory glands in those instances. About ten or more years ago some experiments had been conducted on the effect of injecting the suprarenal extract subcutaneously. With large doses there had been profound disturbances of the nervous system—tremors, clonic spasms, and paralysis of the extremities. The results from administering the gland by the mouth had been vague and, for the most part, negative. Dr. Oliver, who had been using suprarenal extract clinically in persons having a low arterial pressure, had suggested to Professor Schaffer to try the intravenous injection of the gland. The speaker said that he had been in Professor Schaffer's laboratory at the time these experiments had been made, and had noted that the intravenous administration of even a fraction of a milligram was sufficient to double or treble the blood pressure. It should be remembered that there were comparatively few substances which had any very marked effect on the blood pressure. If the vagi nerves were intact, there would be, accompanying this augmented blood pressure, a hyperactivity of the vagi nerves. If these nerves had been cut, the blood pressure would rise still more markedly, and the heart action would be more powerful. Of course, such a rise of blood pressure might be produced in three ways, viz., (1) by the action on the heart muscle; (2) by stimulation of the vasomotor system, whereby all the arterioles of the body would be constricted; and (3) by direct action of the suprarenal extract on the coats of the arterioles. Experiment had shown that it was by this direct stimulation that the suprarenal extract acted, and it was this direct peripheral action that made this drug so valuable a hæmostatic.

The Active Principle.—The speaker said that he had investigated the chemical nature of the substances contained in this gland, which gave rise to the effects just noted. The active principle was a substance which was not changed even by a ten-per-cent. solution of sulphuric acid, but minute traces of alkalies destroyed it very rapidly. At one time he had thought it might be a reduced pyridin, as nicotine and various other substances reduced from pyridin produced an effect very similar to that observed from the suprarenal extract, except that the action was not on the muscular coat of the arterioles, but upon certain ganglion cells. The characteristic odor of pyridin could be obtained by heating the suprarenal extract with alkalies. The most active form was obtained by throwing down all the proteids. With this substance he had secured distinct effects from one milligram per kilogram of body weight. In a great many cases after both glands had been removed from animals, the latter had died very quickly, apparently from surgical shock. An attempt had been made to eliminate this possible source of error by injecting bacilli, and causing a slow degeneration of the gland—an artificial Addison's disease, so to speak.

Mode of Action.—Two theories had been put forward as to the mode of action of the suprarenal gland. One of these was, that the gland formed a substance having a useful function in the human system, *i.e.*, altering the tonicity of the arterioles and of the muscular tissue all over the body. The other theory was, that the effects noted after removal of the gland were the result of auto-intoxication, a substance of a poisonous nature being normally removed by the suprarenal gland. In support of this view it was urged that the blood from the animals from which the suprarenal gland had been removed possessed unusual toxicity.

Note on the Preservation of Aqueous Solutions of the Extract of the Suprarenal Capsule.—Dr. Lucien Howe, of Buffalo, sent a communication with this title. He said that great variations were noted in the different preparations found on the market. His plan was to rub half a drachm of the extract with sufficient distilled water to make a paste. This was placed in a capsule and heated at 160° F. for fifteen or twenty minutes, and the amount of water lost by evaporation was replaced by sterilized water, so that the resulting product still measured one fluid ounce. A little boric acid was then added to this solution. Under ordinary conditions, this solution kept well for several weeks in well-corked bottles. Three other methods of preservation were mentioned. The first of these was by putting up the extract in the form of the so-called ophthalmic discs. The powder was rubbed up into a paste with water, and then sufficient mucilage was added to make the mass cohere into small wafers. Solutions of the extract could also be preserved by formalin, in the strength of one in ten thousand parts. Both of these preparations had the disadvantage of being more or less irritating. The extract also kept apparently indefinitely in a thirty-five-per-cent. glycerin solution, but this preparation was also somewhat irritating.

Suprarenal Therapy.—Dr. W. H. Bates began his paper on this subject with the assertion that in spite of the almost infinitesimal dose needed to produce a recognizable physiological effect, suprarenal extract was not poisonous, its effect was not cumulative, and it had no direct effect on the nervous system. It was not an anæsthetic. Out of the two thousand cases in which the suprarenal extract had been seen to constrict the blood-vessels, in not a single instance had the expected subsequent dilatation of the blood-vessels been observed. All inflamed tissues were benefited by the application of this extract. The effects obtained by the local use of the extract could be obtained, though to a less degree, by the internal administration of this remedy. He had seen congestion of the eye, ear, and throat, larynx, and thyroid gland become decidedly less within three minutes after swallowing five grains of the suprarenal extract. He had controlled nasal hemorrhage in a "bleeder" by syringing the nose with a solution of suprarenal extract, after peroxide of hydrogen, tampons, and other means had failed to check the bleeding. This extract was not an objectionable hæmostatic like iron. Secondary hemorrhage was lessened by the suprarenal extract. The hæmostatic effect was temporary, and it might be necessary, therefore, to use it every two hours for a number of hours. The preparation used must have been freshly prepared to be efficient. He had known the aqueous extract to spoil in one hour.

Effect on the Heart.—It was not uncommon for enough of the suprarenal extract, when instilled into the eye, to be absorbed to increase perceptibly the tonicity of the heart in persons affected with cardiac disease. A number of sphygmographic tracings were shown in this connection. The internal administration of the suprarenal extract did not affect the normal heart or the normal blood pressure, but an intermittent pulse would become regular, and a weak pulse stronger. The author's conclusions were: (1) The aqueous extract of the suprarenal gland, when used locally, was the most powerful astringent and hæmostatic known; (2) congestions of other organs besides the eye were relieved by the internal administration of the extract; (3) it was useful in all forms of inflammation and in all parts of the body; and (4) it was the strongest known stimulant of the heart.

The Treatment of Diseases of the Nose and Throat with the Suprarenal Extract.—Dr. H. L. Swain, of New Haven, read this paper. He said that the extract would not noticeably affect the vessels in which there was not a well-developed muscular coat, or the palsied vessels met with in long-standing and extreme inflammation. On the other hand, the suprarenal extract would always contract the turbinal swellings, and open up the nasal passages. The blood-vessels in these bodies were surrounded by extremely well-developed muscular coats. When cocaine was used, either before or after the suprarenal extract, the greatest possible contraction of the mucous membrane was made possible. Perhaps the most valuable property of the extract in nose and throat work was that it could be used freely, and could be swallowed by the patient without harm. Tolerance was not established, and no drug habit was induced. In hay fever and hypertrophic rhinitis this remedy proved of signal value, when used locally, but he had not been able to observe from the internal administration of the extract the results reported by some other observers. Patients with hyperæsthetic rhinitis were made very comfortable by a thorough spraying once daily with the suprarenal extract. It had also proved quite useful in certain asthmatic attacks arising from nasal pressure. It was useful in conjunction with other measures in aborting or controlling an acute cold in the head. But perhaps the most important field for this remedy was as a hæmostatic in nasal surgery. Whenever there was any removal of tissue, he always made use of it. He had often employed the suprarenal extract and cocaine at the same time, or in immediate succession. Even in the most bloody operations the result was excellent. He could not say conscientiously that he had observed secondary hemorrhage more frequently since using the suprarenal extract than before. For most purposes the freshly made aqueous solution was sufficiently aseptic, but it would be very convenient if some enterprising drug firm would undertake to supply the profession with hermetically sealed glass tubes containing an absolutely sterile solution of the suprarenal extract. He had been disappointed with his results from the internal administration of the suprarenal extract in cases of hay fever. He had used it with the greatest satisfaction in all forms of tonsillitis, and had been able in this way in some instances not only to give patients with quinsy sore throat much comfort, but to enable them to take more nourishment. In acute dry congestions of the naso-pharynx which followed a cold in certain states of the system the suprarenal extract seemed to be especially grateful to the patient. Acute œdema of the glottis reacts most favorably to this agent.

Treatment of Asthma with the Suprarenal Extract.—Dr. Solomon Solis Cohen, of Philadelphia, read a paper on this subject. At the outset he expressed the opinion that asthma was a morbid condition, symptomatic in its nature, and associated with varying and various pathological processes and physical states. It was a distinctly paroxysmal disorder. In certain cases the paroxysm was often the direct result of spasm of the bronchi, both muscular and vasomotor. Abnormal states of the upper respiratory passages and underlying diathetic conditions were responsible in many cases. He had not found the suprarenal exract uniformly beneficial in asthma, as might be anticipated from the varied pathology of this disorder. This remedy had been most serviceable in cases of asthma exhibiting vasomotor ataxia of the relaxing variety, and in those subjects liable to develop urticaria or known to be extremely sensitive to slight changes in climate. The remedy had been chiefly useful in averting the paroxysms and preventing their recurrence. It had rarely cut short the attack, but had proved serviceable by virtue of its ability to remove from the patient the fear and apprehension of the occurrence of the paroxysm. When given internally, it acted well, but the dose must be pushed until some physiological effect is observed. He wished to state emphatically that suprarenal extract was not a specific for asthma.

The Treatment of Hay Fever with the Suprarenal Extract.—Dr. H. Beaman Douglass, who read this paper, was more enthusiastic than the last speaker regarding the effect of this extract in hay fever, declaring that, in his opinion, one was justified in speaking of it as a specific in this disorder. Under the continued administration of this remedy the patient would be in comparative comfort during the remainder of the attack. The cases yielding to it had been benefited equally well by the local and by the internal use of the extract. Some individuals, when taking this substance by the mouth, experienced vertigo or nervous excitement, and observed an increased action of the heart. Naturally, the best results had been achieved in the simple cases, in which the symptoms had been those of nasal and laryngeal inflammation, together with conjunctival involvement. In the cases in which asthma had occurred later as a complication, the asthmatic tendency was certainly diminished or wholly checked by the use of the suprarenal extract. In nasal cases, not accompanied by much congestion, not so much benefit was observed. Cases dependent upon gouty or rheumatic diatheses seemed to be benefited, but in the cases in which the elasticity of the blood-vessels had been diminished by atheroma or by interstitial nephritis, the extract had had little or no effect. The speaker recommended a combination of local and internal treatment. The local administration was best carried out by spraying the parts with a freshly prepared aqueous solution of the extract. Internally it should be given in doses of gr. v. at first, at intervals of two hours, the interval being gradually lengthened, but the remedy should be kept up throughout the entire hay-fever season. No other remedy alone was as useful as the suprarenal extract.

The Use of Suprarenal Extract in Laryngitis.—Dr. H. Holbrook Curtis read this paper. He said that he had made extensive local use of the suprarenal extract. His practice had been to spray the larynx with a freshly prepared solution of the extract, of a strength of thirty grains to the ounce. In a recent case he had secured a most gratifying result in the œdematous stage of a tuberculous laryngitis from insufflations of the powdered extract. In relaxed conditions of the vocal cords the use of the extract seemed to be as beneficial as in the more acute congestions of this part. A practical point, worth remembering, was that peroxide of hydrogen rendered the suprarenal extract inert.

The Treatment of Diseases of the Urethra with the Suprarenal Extract.—Dr. J. A. Moore read a paper on this subject, based on an experience extending over three years, and comprising two hundred cases. The blanching of the urethra produced by this remedy, he said, could be readily observed with the endoscope. In his experience the thick, unfiltered solution had acted much better than the filtered solution of the extract more commonly used. He had also found it more potent when allowed to stand for two hours after its preparation, before using it. He ordinarily employed a ten-per-cent. solution, injecting it with a syringe. In the gradual dilatation of strictures the extract was very useful, as it relieved the muscular spasm. The effect of the remedy was quite transient, so that if more than two sounds were to be passed at one sitting, another application of the extract should be made. By its action on muscular tissue the extract would sometimes sensibly increase the calibre of a stricture. In several cases of meatotomy he had administered a twelve-per-cent. solution of the filtered extract, injecting it into the tissues. In four cases of acute gonorrhœa in which there was severe smarting at urination, the injection of the unfiltered solution gave immediate and decided relief. The unfiltered solution had also proved to be a grateful application in most cases of inflammation of the urethra and when there were ulcers in this canal.

General Discussion.—Dr. E. Larue Vansant, of Philadelphia, opened the general discussion. His experience had taught him that the suprarenal extract, when used in diseases of the nose, throat, and ear, acted as a harmless and most potent non-irritating astringent and hæmostatic, and also enhanced the action of the local anæsthetics usually employed. It was well to remember, however, that the relief was local and temporary, and that other treatment must also be employed. A granular condition of the vault of the pharynx, most often seen in people with wide nostrils, proved especially amenable to the local application of the suprarenal extract, followed by some other astringent, such as one of the salts of silver. There could be no doubt about the efficiency of this remedy in cases of hay fever, but its local administration was greatly superior to its internal administration. He did not approve of using the drug by means of a spray, because of the tendency of portions of the solution to be retained in the accessory sinuses, and elsewhere, to undergo decomposition and so lead to sepsis. This form of sepsis might occur even though the solution of the extract had been perfectly fresh and sterile at the time of making the application.

Dr. R. H. Cunningham said that at one time he had made some experiments with various ductless glands, including the suprarenal. After experimenting upon twenty or more dogs, he had at last succeeded in completely removing the right suprarenal gland and partly isolating and ligating the other gland, though not in removing it from the body. He had kept this dog alive for two years, and had then killed him and examined with the microscope the tiny portion of the gland that had been allowed to remain. He had been unable to find any suprarenal gland tissue. From this experiment he had been led to be rather sceptical concerning the inability of dogs at least to live without a suprarenal gland. He had at one time administered a large quantity of the suprarenal extract to an anæsthetized dog, and had kept a manometer in place for a number of hours, but had been unable to observe the slightest effect on the circulation from this enormous dose. This result was in keeping with the statement that had been made here this evening, to the effect that the remedy did not show its effect on the heart of a normal person or animal.

Dr. R. C. Myles said that he had used this remedy quite extensively, and while the results had been extraordinary, he had not yet been able to formulate definitively in his own mind the standing and value of the extract. He had used the powder in the nose for nearly two years, and did not think he had succeeded in tracing any sepsis to its use. The action on the turbinal tissues was definite, though it did not have any special action on hypertrophies. The effect appeared to be more upon the artery, in contradistinction to the effect of cocaine, which was more particularly on the vein. He had had two quite bad hemorrhages following the use of the suprarenal extract, but, on the other hand, he had been able, with this remedy, to do an almost bloodless operation on the nose in persons who were considered to be "bleeders."

Use in Intratympanic Operations.—Dr. Wendell C. Phillips looked upon the extract as a desirable addition to the materia medica of the nose and throat specialist. He had had some experience with it in cases of suppuration of the middle ear, accompanied with necrosis of the ossicles and a good deal of granulation tissue in the tympanum and attic. In these operations the hemorrhage was ordinarily very free and troublesome. During the part six months he had done a number of such operations after having instilled a solution of the suprarenal extract into the ear, and with a surprisingly small amount of hemorrhage. The operations had been thereby greatly simplified and shortened, thus diminishing their danger.

Secondary Hemorrhage More Frequent after the Extract.—DR. F. E. HOPKINS, of Springfield, Mass., said that, in his experience, troublesome hemorrhage had occurred far more frequently after the use of suprarenal extract than after cocaine. It was also well to remember that this hemorrhage was apt to occur several hours afterward, and at a time when the patient might be many miles away, and far from medical aid. It had seemed to him that there had been fewer cases of prostration since using the suprarenal extract in conjunction with cocaine.

Medical Items.

The Normal Tympanic Cavity is Germ-Free.—The investigations of Zaufal, which taught that the healthy tympanic cavity of rabbits contained the same germs as the oral and nasal cavities, were disproved as far as human beings are concerned by Preysing (*Centralblatt für Bakteriologie*, etc., Nos. 18, 19, 1899), who experimented with the contents of the cavity in recent corpses, and who arrived at the following results: (1) That the healthy human tympanic cavity is absolutely germ-free. (2) Even the cavities (which are filled with mucus) of the newly born are germ-free. (3) The serous exudates which depend on general dropsy are likewise free of germs. (4) The germs of typhus can be the direct cause of an otitis media.

Simultaneous Occurrence of Extra- and Intra-Uterine Pregnancy.—Mand (*Münchener med. Wochenschrift*, 1899, No. 37) describes a case of extreme interest. A diagnosis of ruptured extra-uterine pregnancy having been made, the case was operated upon and the diagnosis thus substantiated. The uterus was found to be enlarged and gravid in the third month, and five months later a living child was born. Mand also gives a résumé of similar cases which have been published. Apart from the interest which attaches itself to these cases, they go to point out a danger which may result from the introduction of a uterine sound in examination for extra-uterine gestation.

Electrical Treatment of Gout.—Th. Guilloz recommends the use of galvanism on the gouty parts, as it increases the nourishment of the diseased tissues and at the same time makes it possible to bring urate-dissolving substances to the affected joints, by means of cataphoresis. He places the gouty joint in a solution of two-per-cent. lithium (carbonate?), in which the positive pole is placed while a broad negative electrode is applied to the back or breast. After five to twenty sittings, in which he used a current of 120–200 milliamperes, he noticed not only a cessation of pain and swelling and a certain resumption of movement, but also with simultaneous use of a high-tension alternating current a pronounced improvement in all the bodily functions.

The Permeability of the Skin in Warm-Blooded Animals.—Vogel (*Virchow's Archiv*, Bd. 156, 1899, p. 566) gives an interesting and important description regarding the power of certain substances in different solutions to permeate the healthy skin. The results varied much. Thus the skin was found not to absorb a one-per-cent. watery solution of potassium cyanide even if the solution were acidified; neither did it allow to pass through it the following: Illuminating gas, alcoholic and watery solutions of chloral hydrate, vapor of ether at 18° C., vapor of chloroform at the temperature of room, watery solution of strychnine nitrate, watery solution of physostigmine salicylate. On the other hand it was permeable to prussian blue, sulphuretted hydrogen, ethyl ether, chloral hydrate in ether, ether vapors at high temperature, chloroform, vapor of chloroform at high temperatures, strychnine hydrate in chloroform, physostigmine salicylate in chloroform, and salicylic acid in ointment with water and ether.

Pain.—Pain of a neuralgic or drawing character in the neighborhood of the heart is found as the result of several causes, as a rule, in the following order of frequency: (1) Pain with palpitation of the heart from the accumulation of flatus in the transverse colon just as it turns to descend. Many patients who go to the physician complaining of heart disease suffer only from this condition, due to fermentation in the large bowel. Again, the pain due to gastralgia, or, as it has been called, cardialgia, may be referred to the heart by the patient. (2) Intercostal neuralgia due to debility. In these cases tender spots will often be found, one in the præcordium, another in the outer edge of the scapula, and a third on the vertebral column. These are sometimes called "spots of Valleix." In other cases the pain will be due to spinal trouble, anæmia, or tight lacing of corsets. (3) Pseudo-angina. (4) True angina. (5) Locomotor ataxia.—H. A. HARE, "Practical Diagnosis," page 559.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended March 10, 1900:

		Cases.	Deaths.
SMALLPOX—UNITED STATES.

NON-MALIGNANT GASTRIC AND DUODENAL ULCERS: WITH ILLUSTRATIVE CASES.

By THOMAS E. SATTERTHWAITE, M.D.,
NEW YORK,
CONSULTING PHYSICIAN TO THE POST-GRADUATE, ORTHOPEDIC, AND BABIES' HOSPITALS.

The widespread interest that has recently been shown in the matter of gastric ulcer, and especially in its treatment, has made it appear to me opportune to publish this article at this time.

Clinically speaking, the relation between gastric and duodenal ulcers is so close, as to their causation, symptomatology, and treatment, that it is proper to consider them together.

Ulcers of the stomach are comparatively rare in this country. While Brinton[1] believed they were found in five per cent. of all autopsies, and his belief was confirmed by the results of 32,052 autopsies made in Prague, Berlin, Erlangen, and Kiel,[2] where, as in Brinton's cases, gastric scars and open ulcers were very properly classed together, these percentages appear not to apply in the United States, certainly not in this vicinity; for Welch found them in only six cases out of about eight hundred in New York City, and I in not more than five out of seven hundred and fifty-two, according to my private records taken from St. Luke's and the Presbyterian hospitals, between the years 1872 and 1888. Da Costa[3] also holds to the view that gastric ulcers are less common in this country than in England. And Ewald[4] has shown that the liability to this disease appears in some degree to be governed by locality, for in northern Europe and Denmark he found that gastric ulcers were comparatively frequent, the percentage rising to thirteen in Copenhagen, while they were infrequent in parts of Russia and Southern Europe. Indeed, Nolte[4] found the percentage in Munich to be as low as 1.23 per cent. It may, however, turn out in the future that a close search for small scars will show that gastric ulcers are more common than these figures indicate. Gruenfeldt[5] has sustained this idea by having found ninety-two, or twenty per cent., of gastric scars in four hundred and fifty autopsies at Copenhagen; but he examined closely for gastric lesions.

Ulceration of the stomach is sometimes divided into the acute and the chronic; a division, however, that has more pathological than clinical value, because we can never distinguish the two during lifetime, except when the ulcer is felt through the abdominal wall by palpation—a rare occurrence—or exposed in the course of a laparotomy. For the same reason we are usually ignorant as to the size, shape, and special characters of the ulcers, though it is common to call them round, eroding, corrosive, etc. But these ulcers are not always round. They may be oval. They erode, but so do cancerous ulcers. The term corrosive applies to a corrosive liquid, but corrosive liquids as a rule produce erosions that heal readily without leaving any scar. However, it is true that a large number of gastric ulcers have a rounded contour with sharp-cut edges surrounded by a zone of tough fibrous tissue, a puckering of the gastric walls about them, and bands of fibrous tissue radiating outward. This variety has been called the acute; as a rule, however, it is merely a form of the chronic variety. On the other hand, the ulcer which has greatly infiltrated walls and ragged shelving edges forming a sort of inverted cone, the apex being at the peritoneal covering of the stomach, is always a chronic variety. There can hardly be much mistaking such an ulcer, when it is exposed to the eye, though it might be taken for a cancer or sarcoma. Indeed, in microscopic section it might be mistaken for a round-celled sarcoma, because in both sarcoma and gastric ulcer there is a great similarity in the character of the round cells. But if the non-malignant ulcer is brought into view, the peculiar excavated centre should indicate its true character.

In taking up the etiology of gastric ulcers we naturally consider the question of age and sex. Brinton in two hundred and thirty-four cases found that one hundred and sixty were females and seventy-four males, and that the average age in women was twenty-seven years, while in men it was forty-two. These points have some practical value from a diagnostic point of view, for while Goodhart[1] has described a gastric ulcer in a child thirty hours old, and one is related by Eppinger[2] in a man over one hundred years of age, the plain fact remains that in gastric ulcer the disease is one of middle life. The periods of greatest frequency have been regarded as between the ages of twenty and forty, and forty and sixty, with some preponderance in favor of the first-named period. But as these views were derived from post-mortem data, they might be somewhat inaccurate, so far as fixing the date of inception of the ulcer, for this point is obviously not determinable by post-mortem evidences. The ulcer may have existed for many years—ten, fifteen, twenty, or perhaps thirty, or even more before its discovery; that is, if we rely on clinical evidence. But we have nothing better, or as good. In this connection, however, it is important for us to know that both the clinical and pathological data fix the period of greatest frequency of ulcer at from twenty to thirty years of age.

Among the causes that have been assigned are:—mechanical compressions, as by corsets, tight belts, pressure against the stomach by the shoemaker's last; injuries to the stomach, wounds of the organ, as by instruments, or in fact injuries of any kind. Gastric ulceration is a common circumstance in tuberculosis. It is also found in anæmia and menstrual disorders, and disturbances of the circulation such as endocarditis and atheroma. The fact that gastritis, scurvy, diabetes, intermittent fever, burns, typhoid fever, septic processes, etc., and the other conditions named, have been assigned as causes of gastric ulceration, only illustrates how obscure the causative factors are in medical minds. For this reason it is instructive to consider the diseases with which gastric ulcers are actually associated. It is now admitted that miliary tuberculosis of the walls of the stomach is generally believed to be rare, though hemorrhages from these ulcers have been fatal. In one of my cases, in which the patient died of hemorrhage by the bowel, I believe the source of the trouble was a tuberculous ulcer. In another case, also seen by the writer in consultation, in which the patient died of inanition, numerous ulcers supposed to be tuberculous were found in the stomach. This experience, therefore, confirms that of Brinton[1] as derived from the statistics of Jaksch, Dittrich, and Engel, who have held that tuberculosis carries off the patient in from nineteen to twenty per cent. of gastric ulcers. But it has been customary of late to reject all cases from our statistical tables if tubercle bacilli were not found in the ulcers. Naturally this course of action invalidates the older statistics; however, Herman Durck [2] has actually found tubercle bacilli in four out of nine hundred autopsies in Munich, the bacilli being in the gastric ulcers. And Letulle[3] has found one tuberculous ulcer in one hundred and eight autopsies in tuberculous subjects. In these cases cheesy changes, giant cells, and bacilli should be expected in the earlier stages. In fact, evidence that tuberculosis is a cause of gastric ulcer is accumulating rapidly. Indeed, I am inclined to think that if special attention is paid to the matter, it will be found that the stomach is very more often the seat of tuberculous ulcer than we now think; and I am satisfied that the anæmia described in these cases is often due to tuberculosis. But it is quite likely that anæmia alone, or chlorosis, or even a sluggish circulation may be of etiological importance, and that the liability to ulcer is increased by tight lacing or mechanical pressure on the organ. Such conditions could cause a localized necrosis eventuating in ulcer.

But there are other prominent causes. Lang[4] found a syphilitic history in twenty per cent. of gastric ulcers, Engel [5] in ten per cent.; and Chiari [6] has described two forms of syphilis occurring in the stomach, the localized or gummatous, and the diffuse. In my first five cases, as recorded in my case books, there was some reason to believe that three of the patients were syphilitics. Typhoid may produce ulcers of the stomach, duodenum, and œsophagus. In one of my cases the patient had suffered from typhoid fever fifteen years before, and it is possible that this ulcer had never healed. Septic or any form of bacterial infection is competent to produce infarcts in the stomach. It is in this way that ulcers of the stomach sometimes follow burns, the causation being similar to that of the duodenal ulcer; the septic matter in both cases being carried from the sloughs of dead tissue. The theory that ulcers may be due to circulatory disturbances is based on sound theoretical principles, in so far as such disturbances are competent to produce embolism, thrombosis, or even hemorrhage anywhere in the body, but as a matter of fact it does not appear that the stomach suffers much from this condition of the circulation, probably on account of its excellent collateral circulation. However, Berthold,[7] of Berlin, has reported that of two hundred and ninety-four cases of gastric ulcer, in one hundred and seventy, or fifty-eight per cent., there were disorders of the circulation, chiefly endocarditis and atheroma, and Steiner[1] found even a larger percentage (seventy-one out of one hundred and ten, or sixty-four per cent.). For the reasons given above, however, it is not likely that these views will be sustained by future investigations. In this connection it should be remembered that simple erosions are probably of frequent occurrence, being often caused by the ingestion of foreign substances or improper food, abuse of the stomach tube, etc. In fact, it has been abundantly shown that foreign bodies, such as knives, bits of glass, broken china, etc., may be swallowed with comparative impunity, and if they make wounds they heal readily and usually without scars. But the most important agent in the development of the ulcer is the gastric juice itself. This being heavily charged with hydrochloric acid is a corrosive liquid competent under appropriate conditions to destroy all albuminous substances with which it comes in contact. How, then, can it be secreted as it is with impunity in the human stomach? This is a question still to be answered, but Pavy has offered a possible solution by suggesting that this acid is neutralized by the blood current, which is strongly alkaline during gastric digestion. But even in ordinary health, if there has been any considerable destruction of the gastric tissues below the level of the epithelial cells, the tissue does not appear to be able to withstand the corrosive action of its own juices. And there are periods when the danger is extremely great, and when the epithelial tissues are themselves acted upon by these same juices. It is when the circulation is very feeble, as during the crises in fevers or in periods of profound inanition during the last hours of life, or after death. There is now no blood current, or it is extremely feeble, and there is therefore no alkaline current sufficient to neutralize the hydrochloric acid of the gastric juice. It is then that gastromalacia, or the auto-digestion of the stomach by the gastric juices, takes place. Another theory is that the acid is resisted by the protoplasm of the gastric cells themselves. Gastromalacia is a rapid process and may extend in a few hours from the stomach to the adjacent organs. I have seen a considerable part of the entire stomach destroyed, precisely as if it had been dipped in a corrosive liquid. In infants, this process is especially frequent, and has been attributed in part to the decomposition of the undigested milk. It is a phenomenon of wasting diseases such as tuberculous meningitis. The gastric ulcer varies in size from the head of a pin upward, but the dimensions are usually between one-half an inch and one and a half inches. I have seen it, however, much larger. Ulcers the size of one's hand have been described. But it is easy to be mistaken on this point. In removing the stomach post mortem, or in separating it from its attachments in the course of an operation, the ulcer may be torn, and frequently has been torn so as to appear larger than it really is, or the inexperienced operator may mistake gastromalacia for an ulcer. Of course we should expect that these errors would not be made by persons of experience, but they do occur. The margin of gastric ulcers is almost always somewhat thickened, and the walls are apt to be perpendicular or sharply outlined. The mucous coat in the so-called chronic ulcer, whose base is turned upward, is the most affected. As the ulcer advances in age, there is usually a progressive thickening of the walls caused by fibroid infiltration and by its subsequent contraction, with which there is to a less degree some hypertrophy or at least some contraction of the muscular coat. It was formerly held that most of the gastric ulcers are either on the posterior surface of the organ or on the lesser curvature. Brinton found in one hundred cases that the ulcer was on the posterior surface or lesser curvature or pylorus in eighty-six per cent.; Welch in 77.9 per cent. from a study of seven hundred and ninety-three cases. Nolte in forty-one cases, however, found the disease located in the greater curvature, anterior wall, or pylorus, in thirty-eight, or ninety-one per cent. If this last percentage is shown to be even measurably correct, it is extremely important from a surgical point of view, opening up great possibilities to the operator.

[1] Steiner. Pepper's "System," vol. ii., p. 487.

The ordinary symptoms of ulcer in the stomach are localized pain after eating, vomiting, hæmatemesis or melæna, or both. There may be also gastric irritability. We should look for all of these symptoms of gastric ulcer; but they may not occur. There may also be the signs of the disease with which gastric ulcer is often associated. Tuberculosis may be present but have no lesion from which we can get the tubercle bacilli. However, in such cases we should expect anæmia and a low count of the red blood cells, or a reduction in the hæmoglobin, even in cases in which there has been no apparent hemorrhage. As syphilis holds an important place among the probable causes, we should look closely for the signs of the disease. Pain is a most prominent symptom of gastric ulcer. There are two places where the pain is apt to be located; one is the epigastrium, and the other is in the back—a later sign. The point of pain is usually well localized, and will vary from an area of one-half inch to one and a half inches in diameter. The painful spot in the back is usually to the left of the spine and over the tenth, eleventh, or twelfth lumbar or first dorsal vertebra. Sometimes it is as high as the eighth vertebra. Another sign is hyperacidity of the stomach, caused perhaps by an irritation of the gastric nerves, producing an excessive secretion of hydrochloric acid. If, however, an ulcer has once formed, or there is the direct stimulus to the formation of hydrochloric acid, and if the motility of the organ is so interfered with that the food is unduly retained, there will be hypersecretion of the gastric juices. And yet, on the other hand, after ulcers have become chronic, the glands may become so exhausted by hypersecretion that they will excrete a diminished amount of hydrochloric acid and pepsin, and so it happens that there may be hypo- instead of hypersecretion of the acid. As a rule, however, subacidity or hypochlorhydria or hyposecretion, whatever name is given it, is a neurosis. The points of pain are aggravated by eating, but are present at all times in the same spot. At first it might be classed as simply epigastric distress, but it is often of a boring character, going through to the back. When the stomach is empty there is little if any actual pain, but after eating there is apt to be some immediate distress, due to the solid food producing irritation; after a couple of hours the pain will be due to the movements of the stomach and the increased acidity due to the pouring out of hydrochloric acid. If the pain does not occur within an hour after eating, the ulcer is probably either in or near the pylorus or the duodenum. Relief comes through vomiting or after the food has been expelled through the pylorus. As a rule, in gastric ulcer pain is to be expected as early as half an hour after eating. Thirst is another symptom. Vomiting is frequent, but may be absent. Hæmatemesis is usually the first sign of gastric ulcer, but it is very inconstant, occurring in from twenty-five per cent. to eighty-five per cent. of the cases. The amount of blood vomited varies; it does not depend on the size of the ulcer but on the size of the vessel. When there is hæmatemesis, there is pretty sure to be melæna later, but when the ulcer is near the pylorus we may have melæna without hæmatemesis. Flatulence is a symptom that is not uncommon. It is due to some one of the causes connected with indigestion. It is one of the exciting causes of perforation. If the vomited matter has the appearance of coffee grounds, the indications are that the ulcer is small. If much blood is lost the ulcer is probably large, but we should not be deceived; a small amount may be vomited and a larger amount pass off by the bowels. The cause of the hemorrhage is apt to be some unusual exertion. The appetite is usually good during the early history of the disease. The bowels are apt to be constipated. Diarrhœa is not a common symptom. There may be merely the symptoms of dyspepsia, but chronic catarrhal gastritis usually accompanies the gastric ulcer. I saw such a case in the practice of the late Dr. Thurman, of this city. His patient had been fairly well till within a few days of his death, when signs of perforation appeared from which he did not rally. At the autopsy it was found that he had a large chronic ulcer on the anterior aspect of the organ under the parasternal line. The ulcer had perforated the organ probably some time ago, through the medium of a subphrenic abscess, and there had been a discharge through the anterior abdominal wall in the left groin; but the sinus had never closed. It was surrounded by a fibrous cord, impervious at the upper end, but in the lower portion lined with a smooth membrane, excreting a serous fluid and capable of admitting a urethral bougie for from eight to ten inches. The patient had been under the care of one of our most distinguished surgeons, but it did not appear that an operation had ever been proposed, although in this particular case it would have been comparatively easy to follow up the sinus, excise the ulcer, and sew up the wound. But it was before the era of laparotomy. In such instances, however, operations have been done by Billroth, Hoffmeister, and Mikulicz, and these three have been successful, according to Weir.[1]

In a great majority of cases ulcer of the stomach involves adjacent organs. Brinton found this to be the case in seventy per cent. It is probable, however, that large ulcers such as have been described can never be cured without an operation. In our diagnosis, we are called upon to discriminate chiefly from gastric catarrh, cancer of the stomach, nervous dyspepsia, hyperacidity, sarcoma, duodenal ulcer, diseases of the pancreas,[2] and the subphrenic abscess that is independent of gastric ulcer. In gastric catarrh there is diffuse pain after eating; tenderness and pain are diffused at first; later as improvement sets in there are more limited areas of tenderness. In gastric ulcer the pain is more distinctly localized; but these statements have, after all, comparatively little value, because in ulcer there is usually more or less chronic gastritis and the pain is not always localized. Hæmatemesis is a marked symptom; in catarrh it is usually absent, and is never profuse. In gastric catarrh, if chronic, there is usually dilatation, and it may be extreme. There is little dilatation in gastric ulcer. The vomit in catarrh is mostly mucous. In nervous dyspepsia the pain is relieved by pressure. It is sharp and shooting, and usually occurs when the stomach is empty. The pain is relieved by stimulants, while in gastric ulcer it is increased by stimulants. This gastralgia is seen in hysteria, melancholia, and other nervous affections. There is no hæmatemesis or melæna in nervous dyspepsia.

In this country carcinoma of the stomach is much more common than the malignant ulcer. It is usually a disease of middle age or above it. There are vomiting and sometimes hæmatemesis. The vomited matter is apt to be offensive. There is usually some emaciation, though not always, but the distinctive sign is a tumor that can be felt. When recognized positively by palpation, it may be confidently said that the patient will not live more than six months. Cancer is a progressive disease without intermission. It is sometimes said that gall stone may be mistaken for gastric ulcer. It is more correct to say that abscess of the liver, due to cholecystitis, may be hard to differentiate from subphrenic abscess caused by perforation of the stomach. The history of the case is most important. In gall stone, the pain is violent and brief and distinctly localized. It is apt to be accompanied or followed by an attack of jaundice, and the liver will be tender and swollen. Sarcoma of the stomach is rare, but a number of cases have been reported. It may be primary or secondary, nodular or diffuse. The onset is usually insidious. There may be anorexia, hæmatemesis, or melæna. As yet, however, we have no clinical signs that will permit us to differentiate this neoplasm from other conditions. However, if a tumor can be felt, and the spleen is enlarged, the disease is probably sarcoma, more especially if a sarcoma has been removed by surgical operation. Carcinomas and sarcomas do not, in my experience, ever occur contemporaneously in the same subject.

[1] Medical News, May 2, 1896, p. 488.

[2] A case of hemorrhagic pancreatitis has been mistaken for gastric ulcer (Maurice H. Richardson: Philadelphia Medical Journal, February 2, 1900). Laparotomy was done, and the patient recovered.

The prognosis as to eventual cicatrization is doubtful, notwithstanding the favorable opinions of some eminent writers. Brinton says that perforation did not occur in eighty per cent. of his cases. That ulcers will heal is shown by the scars found at post-mortem. Thus, in 11,888 bodies, 164, or 1.04 per cent., had open ulcers, and 373, or 3.01 per cent., had scars, which would make at least sixty-nine per cent. of cures. According to the consolidated statistics of Dittrich, Jaksch, Welling, and Dahlerub,[1] in 303 cases of healed and unhealed ulcers, there were 147 scars and 156 open sores, so that at least in fifty per cent. cicatrization had been accomplished. According to Debove and Remond, cures may be found in fifty per cent., the causes of death being tuberculosis twenty per cent., perforation and peritonitis thirteen per cent., hæmatemesis five per cent., inanition five per cent., complications seven per cent.; a total of fifty per cent. Welch puts the danger of perforation at 6.5 per cent. Patients will sometimes get well without treatment.

Treatment.—In so far as treatment is concerned, two things should be prominent in one's mind: first, to relieve immediate symptoms; second, to cure the ulcer. In hæmatemesis one cannot insist too strongly on rest in bed, and that the patient must not get up for any reason whatever. No food should be taken by the mouth, and in fact no liquid should enter the œsophagus. The lips may be bathed in water. If hemorrhage continues, some preparation of ergot should be used, perhaps followed by morphine in gr. ¼ doses. An ice or cold-water bag should be applied to the stomach. In case of collapse, transfusion should be made with decinormal salt solution. During this period the patient should be fed by the bowel. Six ounces of peptonized milk should be given every three or four hours. At the end of three days a little liquid may be given by the mouth, *i.e.*, milk, lime water, beef tea, or the peptonoid. At the end of the week the patient should be put on a regular diet, and kept in bed. The bowels should be moved by laxatives, such as Apenta water. Warm applications should be made continuously to the epigastrium. After two weeks the patient may be allowed to get up, but food likely to distend the stomach should be avoided. The stomach should never be washed out or the tube used in gastric ulcer; profuse hemorrhage may occur with all its attendant dangers. There is, I am sure, much harm done sometimes by unskilful washing out of the stomach. Large pieces of mucous membrane may be caught in the eye of the tube and torn out. Bits of mucous membrane are so frequently found in the wash-water as to lead to the supposition that they were torn off by the tube. In fact, at post-mortem examination I have seen in a single case numerous erosions of the stomach caused by lavage. Operative measures have been frequently resorted to, and especially during the last few years.

But, as will be seen, it is difficult to make a fair comparison between the medical and surgical results that have been reported thus far. When Weir and Foote published their paper,[1] there appeared to be no reason to prefer surgical to medical methods, for the surgical mortality in their seventy-eight collected cases was set at 71.51 per cent. Apparently the surgical outlook is now better, for Tinker[2] reports that one hundred and thirty-one cases he has collected since the former date show a surgical mortality of only 35.71 per cent., while individual surgeons are now known to have reported still better results. Thus, Haberkant's show a surgical mortality in gastro-enterostomies of only twenty-five per cent.[3] Further, of Tinker's cases thirty-seven operated on during the first twelve hours showed a mortality of only sixteen per cent.; in pyloroplasty of 13.2 per cent.[4] The French surgeon, Doyen, in his book[5] puts his mortality after gastro-enterostomies at ten per cent., while W. S. Mayo, of Minnesota, reports that he had only one death in fifteen gastro-enterostomies, a mortality of 6.6 per cent.[6] Accepting these statistics it is plain that the dangers from surgical interference are becoming gradually less and less in certain classes of operations, so that the counsel of the surgeon may be well invoked by the medical practitioner in these cases. In fact, in suspected cases of gastric ulcer the physician and surgeon should work together, mutually aiding one another in diagnosis and in deciding the question as to whether an operation is advisable or not.

For on the medical side of the case it must be recognized that the mortality from medical treatment is probably quite small. Weir and Foote once put it at twenty per cent.[7] On the other hand, a recent writer[8] puts it at only five per cent.; while Leube, of stomach fame, has stated publicly[9] that in five hundred and fifty-six of his cases he has lost only twenty-two per cent. by death, and four per cent. represents his failure to cure.

It would not be proper to let the opportunity pass of emphasizing the statement, that a surgical operation is the only possible resort in some cases, if life is to be saved.

But all is said and done, and although, therefore, surgery seems likely to gain new laurels in the treatment of gastric ulcer, especially in complicated cases, or if the operations be done very early, medical practitioners will still be content in uncomplicated cases to employ established medical methods, and will have a good share of success.

The most dangerous complication is peritonitis, and it is extremely important to be able to recognize this condition at the earliest possible moment. Palpation ought to show a little tenderness over the ulcer. Peritonitis sets in with a chill, a rise of temperature to 100 or 102 F. The patient lies with the knees drawn up, and has the characteristic facies. The pulse is rapid and small. It is now that surgical relief is to be sought at the earliest possible moment.

Subphrenic abscess is another complication that is also very important from a surgical point of view. It may be dependent on or independent of gastric or duodenal ulcer, but it is most frequently caused by perforating ulcer of the stomach or duodenum. Other causes are ulcerated appendix, abscess of the liver or kidneys, or various intraperitoneal troubles; it may also be due to extraperitoneal influences. I have described such a case as a sequel to empyema.[1] Subphrenic abscesses are apt to be so large as to push down the stomach and the spleen on the left side and the liver on the right, raising the diaphragm up to the level of the third or fourth rib; they may even perforate the diaphragm, causing empyema, or burst through the lungs into a bronchus and so discharge their contents. In a large number of cases these abscesses contain gas, owing in part to communication with the stomach, or to the decomposition of their contents. At first the signs will be gas in a sac containing liquid associated with a perforated ulcer of the stomach or duodenum, together with pain in the epigastrium, possibly a gastric tumor, and the signs of local peritonitis. The differential diagnosis must be made from empyema, simple abscess of the liver or spleen, or pneumothorax. Theoretically the upper level of the diaphragm should in subphrenic abscess be concave, with the concavity upward so that the upper limit of the abscess should correspond to this upward curve of the diaphragm. On the other hand, in simple empyema the curve of the diaphragm should be downward.[2] In these cases of subphrenic abscess, according to Penrose and Dickson,[3] including the thirty-four cases collected by Weir with fifteen cures, Nowak estimates his cures at fifty-five per cent. The treatment should be incision with or without exsection of the rib and drainage. I should be disposed from my experience to recommend through drainage as originally recommended by Chassaignac.[4] If the diagnosis of a subphrenic abscess is made, a surgical operation should be considered at once.

There is no difference in anatomical characters between the ulcer of the stomach and the duodenum; in fact, the non-malignant ulcer that has been described, with its sharply cut edges and rounded contour, may be found as well in the duodenum and œsophagus as in the stomach; for the gastric juices can under appropriate conditions act in all these localities. In fact, the causes of the one ulcer are equally well those of the other, except perhaps that burns have a special tendency to be associated with duodenal ulcers (in from twelve per cent. to four per cent. of burns). As in the stomach, these ulcers are usually found in a middle period of life, but there is this difference, that in men they are three times as frequent as in women. Duodenal ulcers are usually found near the pylorus on the inner or posterior walls of the bowel. In a large number of cases there will be no symptoms; in about 12.5 per cent. ulcers of the duodenum and stomach will be associated together. In one hundred and fifty-one cases of duodenal ulcer collected by Perry and Shaw[5] there were no noticeable symptoms. So far, however, as we are able to decide, symptoms of pain come on later than in gastric ulcer. If it occurs in from four to five hours after eating, duodenal ulcer is probable. There is also more or less pain to be expected over the right lower border of the liver. This pain radiates and may go through to the back. There is no tumor, but there may be a painful spot. If the patient takes no solid food, the pain may stop. As in gastric ulcer, hemorrhage is an important sign. If the food is first vomited without blood, and blood follows, the indications are that the difficulty is below the pylorus. There will also be obscure dyspeptic symptoms. The prognosis is more unfavorable than in gastric ulcer, because the disease is less easy of reach.

The following are some illustrative cases taken from my hospital and private records:

Case I.—Probably syphilis of lungs and liver; ulcer of stomach; death following hæmatemesis. L. St. R——, aged forty-two years, admitted September 18, 1882. The patient had some chronic sore throat. The hair had fallen out in large quantities. She had been tapped for ascites. Eleven days after admission to hospital she had melæna, followed by hæmatemesis. Hypodermics of ergot were given without avail, the patient dying of collapse. At the autopsy, the whole gastro-intestinal tract was found congested, while the sigmoid flexure and rectum were found thickened. At one point in the stomach there was a superficial ulceration. This case illustrates the fact that a very small ulcer may be the seat of a fatal hemorrhage. It was probably syphilitic.

Case II.—Chronic tuberculous ulcers of the bowels; catarrhal gastritis. A. R——, aged thirty-six years, admitted to hospital October 14, 1886. For the past five years the patient had suffered from pain over the pylorus and vomiting after eating. The pain had not been constant, but was marked after taking food. The order of symptoms had been, after a meal, pain, nausea, and vomiting. There never was any hæmatemesis. The patient was taken with severe epigastric pain and also vomiting, with severe intestinal cramps and abdominal soreness. A second attack occurred three months later. Two months ago, he had another attack. The pain he described as if the intestines were twisted or knotted. The stomach would retain nothing, not even ice water. Constipation and flatulence were present. Rectal injections could not be retained. The mouth and throat were swollen; vomiting of greenish matter occurred. The patient became delirious, collapse ensued, and he died on the third day after admission. No history of tuberculosis or syphilis had been obtained from him. At the post-mortem the lungs were found infiltrated with tubercles, and the mesenteric glands were cheesy. Tuberculous ulcers were present from the duodenum downward through the entire length of the intestine. In this case the patient died of ulcerative enteritis, while the stomach was merely in a condition of catarrhal gastritis. This case is especially interesting as showing the difficulty of distinguishing enteric from gastric ulcer. It was never suspected that his disease was anything but gastric ulcer, until the autopsy showed the error.

Case III.—Tuberculous phthisis; duodenal ulceration, etc. G. H——, aged twenty years, porter, admitted to the hospital May 6, 1880, was found on examination to be emaciated and in the third stage of phthisis. He had hectic and night sweats, with chronic diarrhœa. The patient died of exhaustion fourteen months after admission. The bowel was studded with ulcers from duodenum to cæcum, as shown by post-mortem examination. This case and the preceding one show that tuberculosis plays an important part in ulcer of the duodenum.

The two following clinical cases from my practice are sufficiently interesting to be detailed:

Case IV.—Ulcer of the stomach and intestine; typhoid fever; tuberculosis; membranous enteritis. The patient was put under my care by a physician April 12, 1898. The history was as follows: A. K——, aged nineteen years, had been delicate all her life. She had "enteric fever" in August, 1897, which lasted four weeks. A month later she had intestinal colic. Still a month later she began to cough, and diagnosis of acute tuberculosis was made. She had a daily rise of temperature, with night sweats, loss of appetite and flesh. Throughout her sickness a good deal of pain occurred in her stomach, coming shortly after meals. Iron, bismuth, silver, etc., did not relieve her. Menstruation was suspended for eight months. There was no vomiting. On examination it was stated that she had lost twenty pounds during the year. She complained of pain in the epigastrium after eating, with occasional flatulence. There was no movement without medicine, but Hamburg tea relieved her constipation effectually. She vomited food; there was pain on pressure over the centre of the stomach. Physical examination showed consolidations of both apices, as also scattered areas in both lungs. The pulse was weak and intermittent. The temperature was 99.8° F. Small doses of calomel stopped vomiting. Complete mental and physical rest was ordered, with some such nutrient as marrow, the prepared infant foods, and malt preparations, of which maltzyme was especially satisfactory. Carefully selected and nutritious foods were also prescribed at intervals of two hours, so that she took something six times a day. Starchy food was excluded as far as possible. Gradually, as her strength came to her, she was allowed to take short walks. This treatment was kept up for twelve months, at the end of which time she was gradually permitted to return to the regular diet of a woman in health. She had gained sixteen pounds. She now (January 30, 1900) has the general appearance of health, rides her wheel, and is constantly gaining flesh. Epigastric pain is only occasional, and this is caused by gaseous distention.

[5] Guy's Hospital Reports, 1892, vol. i.

Case V.—Gastro-intestinal ulceration; chronic gastritis, endocarditis; lateral curvature. In April of 1898 I saw in consultation a lady who had been under treatment for several years and had consulted many eminent practitioners both at home and abroad. Several summers earlier she had suffered from what was called acute gastritis. She then vomited blood. A diagnosis of cancer of the stomach was made, and a surgical operation was proposed. She had been suffering from mitral endocarditis and interstitial nephritis, but during a recent trip in Europe had gained some ten to fifteen pounds. After her return an attack of influenza ensued, and exposure to cold brought on a fresh exacerbation of nephritis. I found her much emaciated and suffering from gastric and abdominal pain increased by pressure. The liver was not enlarged. There was no thickening over the pylorus. Owing to emaciation the stomach could be accurately mapped out. From the duration of the disease and the absence of tumor, I excluded cancer. The heart's action was tumultuous. Her hands and feet were cold. The pulse at the wrist was almost imperceptible. The heart apex was carried to the left. There was much food undigested. Relief was given by kneading the bowels and continued application of warm compresses. Some improvement followed the use of the subgallate of bismuth and the tincture of adonis vernalis in doses of ♏ i., together with calomel followed by codeine. The sarcopeptones were retained. Stimulants were also given freely. The patient was greatly improved, when an accident happened on the third day after I first saw her; though admonished to keep perfectly quiet and not to rise from her bed for any reason, she insisted on rising, and during the exertion a large quantity of blood escaped from the bowels. Death followed at once.

Case VI.—Disseminated tuberculosis with tuberculous ulcers of stomach. I had the opportunity of seeing another interesting case at Bedford Mills, N. Y., in the practice of Dr. J. F. Chapman, of Katonah, N. Y. Miss M——, aged fifteen years, I found confined to her bed with all the symptoms of acute general tuberculosis. The case was beyond the reach of medical skill. The diagnosis was confirmed by the autopsy, the peculiarity being in this case that while the family give no evidence of tuberculous taint, the daughter was an extreme example of tuberculous infection, with numerous tuberculous foci in the stomach, in addition to those of the mesentery and peritoneum.

I should add that in these cases classed as tuberculous no bacilli were found, because at that time the tests for bacilli were unknown, but there was no doubt in my mind that they were tuberculous.

7 East Eightieth Street.

ON THE TREATMENT OF FATTY HEART.

By PROFESSOR TH. SCHOTT, M.D.,

BAD NAUHEIM.

In attempting to give the treatment of fatty heart I shall relate my own experience and also the changes which have occurred in the therapy of chronic heart disease in the course of the past century. We shall see that different theories have led to different modes of treatment.

Three varieties of fatty heart are generally recognized, viz., (1) that in which the fat lies as an overgrowth or penetrates between the muscular fibres, so that large quantities of fat are found covering the pericardium or underlying it, quite enveloping the heart. This condition may be observed at the apex, in the sulci of the large cardiac vessels, especially at the sulcus transversus and the base of the heart. The fat may even penetrate between the muscular fibres as deep as the endocardium. (2) Fatty degeneration of the muscle, in which more or less numerous globules of fat are intermixed with the muscular tissue and the action of the cardiac muscle is thus weakened. (3) When the fat tissue fills up, as it were, the lacunæ of the muscular substance; this is to be seen in hearts the muscular walls of which are quite enfeebled, and in which, as a consequence, the fat penetrates into the muscular substance, or in hearts which have become atrophied by myocarditic processes, and in which the fat is found in the lacunæ of the fibrous tissue. These globules of fat appear to the eye like yellow spots of various sizes. In this condition the fatty tissue is only accidental and has nothing to do with the original disease process.

That which we usually understand by a "fatty heart" is either an overgrowth or intermixture of fat, or it is a condition of fatty degeneration of the heart muscle. Not infrequently we find these two conditions coexisting and in a state of transition, so that it is difficult to distinguish one form from the other.

I shall now endeavor to consider fatty heart, properly so-called, viz., the first-named variety, with its transition to the second.

As we have no unequivocal symptoms of fatty heart, we are obliged to arrive at a diagnosis by a combination of conditions, by general observations, and by especial heart symptoms. Thus, a fatty heart may be diagnosed if the following conditions are detected: an easily induced sensation of fatigue in a person having an abundant deposition of fat over the body in general, or more especially upon the chest and bowels, with difficult breathing, amounting at first only to a slight oppression and ending in dyspnœa, with small feeble, frequent, and easily compressed pulse, with final dilatation of the heart, and when through weakness of that organ, or owing to the effect of an accumulation of fat around it or in its walls, the ictus cordis begins to disappear; further, a condition of general plethora, or fulness of the skin, and a sense of straining in the bowels, etc. But all these symptoms cannot be regarded as absolutely unmistakable signs, for I have met with many cases in which these symptoms were due to weakness of the heart caused by chlorosis or anæmia, overexertion, mental excitement, coitus nimius, or to the abuse of coffee, tea, alcohol, etc., all of which excesses it is known either weaken the cardiac muscle or affect the nerves of the heart. Only long experience will enable the practitioner to avoid erroneous conclusions, but in general we may say that the diagnosis of fatty heart is made rather too frequently. He who has patients under his observation for a certain length of time will be less liable to make a serious mistake in this respect.

The prognosis depends chiefly upon the state of the cardiac muscle, the duration of the disease and its symptoms, and, further, upon the etiology, age of the patient, etc. The stronger the heart muscle, the less advanced the state of degeneration, the younger the patient, the more normal the blood, the better will be our chance of curing the evil. The graver the symptoms, the more may we expect their temporary amelioration to be followed by relapses, and these are especially to be feared in old people suffering from a fatty heart and in whom other disorders are present. With the improvement of the system of treatment of chronic diseases of the heart, the prognosis of these cases has become much more favorable than formerly.

The prophylaxis plays an important part with such patients. In those cases in which, owing to heredity or to individual disposition, there exists a tendency to obesity, early attention should be given to physical exercise and to moderate mental activity, with such regulation of the diet as to prevent additional accumulation of fat. Whenever the physician has reason to diagnose the first stage of fatty heart, he should forbid the patient doing anything which might prove injurious to or weaken the heart, lest some degeneration of the heart muscle may already be present or about to occur. As all these precautionary measures will have to be spoken of in the general treatment of fatty heart, I need not dwell upon them at present.

Therapy.—It will not be uninteresting to recall, for a moment, the systems of treatment which have formerly prevailed. Before all others the means depended upon were of a pharmacological nature, especially such drugs as caused either nausea or vomiting; at a later period, bleeding was relied upon. Notwithstanding that these measures and remedies not infrequently resulted in collapse and weakness of the heart, or in prolonged periods of anæmia and chlorosis, yet they continued to be resorted to for a long time until they were supplanted by drastic purgatives; but these also were attended by so many dangers that they fell into disuse and gave place to the use of purgatives of a milder nature, which in their turn yielded to the employment of the modest mineral waters. The enumeration of remedies formerly resorted to would be imperfect, did I not mention the preparations of iodine, the use of which had many adherents. Although these preparations are still advocated by a certain number of practitioners, I must not fail to mention that all the salts of iodine are apt to destroy the albuminates, and by their irritant action upon the mucous membrane of the stomach and intestines so impair the appetite that their administration, if relied upon at all, should be reduced to a minimum. Another drawback to their use is the fact that they are more likely to reduce the general obesity than the fatty condition of the heart. The same objections apply to the lately recommended preparations of thyroidin. Doubtless in a certain percentage of cases their use has resulted in a more or less satisfactory decrease of fat, but this result, as I have of late had repeated occasion to demonstrate, is accompanied, in patients suffering from fatty hearts, with considerable danger, for the effect upon the cardiac muscle and upon the nervous system is such that death may result. Thus there may occur tachycardic attacks, dilatation of the heart muscle, insomnia, and nervous excitement amounting at times to mania. As regards oöphorin in tabloids, which during the past year has been recommended for the treatment of obesity in females and also for cases of fatty heart at the climacteric years, I must defer giving an opinion, at least for the present. A quarter of a century ago the principal rôle in the treatment was played by the mineral waters, and chiefly such as contained sulphate of sodium, like those of Marienbad, Karlsbad, Tarasp, etc. Especially were the springs of Marienbad relied upon, and they are still visited by many in the treatment of general obesity with a fatty heart. But even at these springs we no longer see, as formerly, that avidity in the use of the waters in order to obtain in the least possible time the greatest decrease in weight. The dangers of such a course of the waters were not infrequently such as even to threaten life, for patients have come to me from these springs, when in a course of four to six weeks such a loss of weight in proportion to the bulk of the body had been caused, that a rapid and marked diminution of the strength had resulted. One of my patients, who had previously been sent by her physician to Marienbad, was seized during her second week of treatment at that place with an acute attack of œdema of the lungs, and had to be sent home in a most critical state. The mineral-water treatment brings dangers to the heart which will be spoken of hereafter, but general debility, chlorosis, and anæmia, etc., are not infrequently caused by such prolonged purgative measures. There is a still further drawback in that if other modes of treatment are added to prevent a further accumulation of fat, the patient upon his return home is sure to have a return of the obesity. The injurious effect of such forced cures by the use of mineral waters containing sulphate of sodium caused many to abandon their use, and to turn for relief to such saline waters as those of Kissingen, Kreuznach, Nauheim, etc. But even these waters have been used in too large quantities. Formerly, I frequently met with patients for whom seven to nine glasses daily had been prescribed, each glass containing eight ounces of a one-and-a-half-per-cent. solution of salt. While it was not to be feared that such daily quantities of these waters would cause an immoderate reduction of weight, their use not infrequently brought about a gastric catarrh to which obstinate constipation was often added, requiring the active interference of the attending physician. To the late Beneke is due the credit of having been the first to draw attention to the fallacy of such severe procedures.

In the last half-century the method of treatment of fatty heart has been revolutionized. Entirely new procedures have replaced the old ones. The two names I must first mention are Stokes and Banting, or, more correctly stated, Harvey-Banting. To the first we owe the mechanical and to the latter the dietetic treatment. Both systems now not only form the basis of the therapy, but have been further developed in different directions and supplemented and made more efficacious by new methods. First, as to the dietetic therapy: The fundamental idea of the Harvey-Banting system was to inhibit further accumulation of fat in the body by means of abstinence from carbohydrates and from fatty food, and to impede the transformation into fat by the use of increased quantities of albuminates. Bearing in mind the perfectly reliable investigations of Pettenkofer and Voit, I feel thoroughly convinced that the total food supply prescribed by the originators of this system is insufficient in nitrogen to maintain the normal quantity of that element in the body, or, in other words, that the excessive supply of albuminates certainly leads to a decrease of fat, but causes at the same time a dangerous reduction of the albuminates of the body. The injurious effects of such a Harvey-Banting cure became but too soon evident in the supervention of general nervousness and debility, by insomnia, etc., and a baneful influence was produced on the functions of the heart by a weakening of the cardiac muscle. Furthermore, the excessive ingestion of albuminates may cause disturbances of digestion, and the predominance of nitrogen in the food has in some cases resulted in symptoms of a toxic nature; not infrequently gouty affections are thereby either evoked or increased in severity. It is not to be wondered at, therefore, if at the present time the Banting cure is but rarely recommended by a prudent practitioner. The modification suggested by Ebstein, who instead of albuminates increases the quantity of fat taken by the patient, may be called a system of insufficient feeding with all its dangers, and has therefore but few advocates. It is hardly necessary to mention the old ideas of Schroth, who prescribed dry bread exclusively, or those of Tarnier, who allowed nothing but milk, for they amounted in reality to forms of starvation with all their fatal consequences.

Among all these dietetic formulæ those of Oertel are most in harmony with the physiological statements of Pettenkofer and Voit, but unfortunately he combined with them a severe reduction of liquids, an idea first advanced by Dancil, and the well-known climbing system, which I shall discuss later. Oertel applied his system to cases of heart disease with or without obesity. However rational his system of treatment may at first appear, experience has shown that it is not without danger to the patient, the more so because he failed to differentiate between the use of alcoholics, effervescent beverages, and plain water. He, moreover, frequently reduced the fluids to such an extent—as low as twenty ounces pro die—that an injurious effect was sure to result. His view, too, that he could thus diminish at will the volume of the blood has proved erroneous. I shall state later what cases may be benefited by the use of the Oertel cure, but it may be mentioned here that I and many others have distinctly learned that the very condition which Oertel strove to prevent, an insufficiency of the heart-muscle, has certainly resulted from a pursuance of his treatment, and has been accompanied by dyspnœa, dyspepsia, insomnia, and in some cases by nephritis. Hence the Oertel cure has lost many of its adherents. Of all the systems of reduced diet in the treatment of obesity and of special heart diseases which have been proposed of late years, it may be said that they are dangerous. Many are apt to forget that a fatty heart is a heart weakened by muscular insufficiency. From what precedes we may conclude that no diet cure hitherto proposed is of itself sufficient either to prevent the development of a fatty heart or to benefit one without injuring the patient in other respects. In all cases of reduction of the fatty tissues we run the danger of at the same time diminishing the albuminates, whereby the muscular and nervous systems are sure to suffer. It is not a matter of indifference which organs are deprived of the albuminates, for the loss of a few grams of the cardiac muscles may do more harm than the reduction of as many pounds of albumin in some other part of the body, as, for example, in the extremities.

With our present knowledge we cannot, after a reduction of the albumin of the body has been brought about, state whence that constituent has been taken, nor do we know of any remedy to prevent a loss of a part of the muscular substance of the heart. Experiments upon animals have taught us that by starvation it is difficult to diminish the fat in or about the heart. We learn that the fat and the muscles of the body may be largely reduced without any appreciable diminution of the heart fat. Be it therefore understood that we cannot altogether dispense with dietetic measures, but they must be combined with other therapeutic procedures, of which the first to be mentioned is the

Mechanical Treatment.—This mode was first introduced by Stokes. He had noticed that people with fatty hearts suffered when climbing mountains, at first from dyspnœa, but that later, as he so well expressed it, "they got their second wind," and were then able to attain their object without being harmed thereby. But this mountain-climbing as a sole method of treatment soon fell into disuse and was abandoned on account of injurious effects which often resulted, and because of the violent opposition to it by scientific men. Many physicians then went to the other extreme and advised their patients to indulge in excessive rest, until about fifteen years ago, Oertel, having tried the Stokes system on his own person, endeavored to systematize mountain climbing by organizing in different places certain climbing excursions, better known under the name of "Terrain Kuren" (climbing cures). These consisted in various paths whereby the patient was at liberty to choose in gradation those of a level nature and others with more or less of a rise, while the character of still others was quite steep. Even this method was found to be followed in many cases by injurious consequences, giving rise to violent opposition—the reasons for which I shall speak of later—so that the number of those who prescribe the climbing according to Oertel's method has rapidly decreased.

Of late years a large number of apparatuses have been invented, having in view the diminution of fat by an increase of the muscular functions, and thereby a strengthening of the cardiac muscle. I will merely mention that of Gaertner, the rowing-machine, the contrivances of Nicander, the different chest exercises, etc.; but all these expedients were unable to rival the machines invented by Zander. I do not purpose to discuss their value here, having done so in previous publications in which I have called attention to their shortcomings; whether the apparatus lately invented by Herz can overcome the defects of the Zander machines remains yet to be seen.

The gymnastic treatment, first brought into notice as a therapeutical measure by my brother, the late August Schott, and by myself, consisting, as the readers of this journal know,[1] of exercises with resistance or self-resistance, can unhesitatingly and safely be resorted to in all the different forms of fatty heart. Provided the degenerative process is not too far advanced, and there are no other complications, and the age of the patient is not too far advanced, we begin at once with a resistance of middling strength, increasing rapidly to a vigorous resistance. The long rest generally taken after these exercises is not so requisite in the treatment of fatty heart. Of course such patients must take abundant exercise in the open air, but the climbing of mountains should not be allowed until the heart shows increased muscular strength and a more normal functional activity. As my brother and I have always declared, the climbing of mountains may form the ending but never the beginning of the cure, as only thus do we avoid the danger of overstraining and further weakening of the heart. On the other hand, we have to guard against too much rest;

[1] Vide Theodor Schott: "Balneo-Therapeutics and Mechano-Therapeutics in the Treatment of Chronic Heart Disease," New York MEDICAL RECORD, February 14, 1891; "Treatment of Chronic Diseases of the Heart in the Light of Roentgen Rays," New York MEDICAL RECORD, March 26, 1898; "On the Treatment of Cardiac Neuroses," New York MEDICAL RECORD, March 11, 1899.

it is well known that all stout people incline to physical laziness, especially after meals. In order to bring about a diminution of weight and of fat, rest should never be indulged in after eating. If there be need of repose, the patient should lie down for a while before the meal and take a walk after it. This procedure alone will benefit those suffering from obesity and especially persons afflicted with a fatty heart. In combination with these physical exercises, massage will prove an efficient expedient for promoting the absorption of fat, but without exercise massage is unavailable for this purpose, and the reasons therefor I hope to demonstrate to my readers in a future paper.

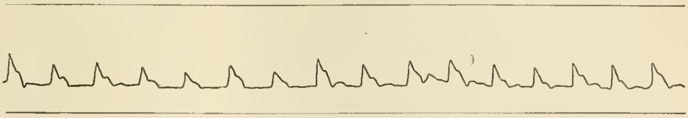

Fig. 2.—After Twenty Minutes' Exercises with Resistance.

Balneological Treatment.—In this field during the last decennium the application of the balneological and hydrotherapeutical treatment has been found to be of the greatest value. Hydrotherapy is preferably resorted to in the form of potations or douches, but with patients suffering from fatty heart extremes of temperature, high or low, may prove dangerous and should be avoided. The readers of this journal are doubtless familiar with the balneological method introduced by my brother and myself, and I will therefore merely state that when the degenerative process is not far advanced we can without fear proceed with baths of gradually increased concentrations of salt, as well as with baths with increased quantities of carbonic acid gas, and it is especially with fatty-heart cases that we can have early recourse to the use of Sprudel- and Sprudel-Strombäder (effervescent running-baths). Unless there are contraindications thereto, such as chlorosis and anæmia, rheumatic or arthritic complaints, or advanced age, all of which require a warmer temperature, we may with better advantage begin with the baths of low temperature. I generally order at first a temperature of 88° to 86° F., and gradually get down to baths of 77° to 76° F. The duration of the bath at the commencement of the course is usually ten minutes, and the bath is at first intermitted on the second day, and afterward every third or fourth day. The duration of the bath is gradually increased up to twenty minutes. I have rarely seen good results from a longer duration. Those cases of fatty heart associated with chlorosis and anæmia are especially and very rapidly benefited by various effervescent baths which I have mentioned.

The balneological-gymnastic method in combination with the dietetic treatment is undoubtedly the agent which to-day is most relied upon in the therapeutics of fatty heart, and the question arises, Have we better and more successful results by their use and application? Judging from my large experience in this field it is without hesitation that I can answer this question in the affirmative, so that I may say that the prognosis of fatty heart has now become much more favorable.

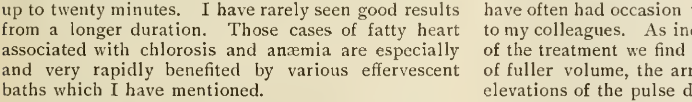

Fig. 1.—Before Treatment.

While with all the older methods of treatment which I have mentioned a diminution of the albuminates of the body was brought about simultaneously with the reduction of fat, we are now able to cause the fat of the body to be gradually consumed, while at the same time the muscular substance is not only spared but is frequently augmented, and the volume of the blood is increased. Thus, it may happen that the patients gain in weight, although a decrease of the panniculus adiposus and of the abdominal masses of fat may be clearly demonstrated. I have repeatedly described such cases in my writings, and among them have called especial attention to a patient suffering with kyphoscoliosis—a case exactly similar to that which Oertel enlarged upon with so much enthusiasm—who lost his fatty heart and all the symptoms connected therewith, without any loss of the weight of his body. But I must here energetically warn against a rapid loss of weight, especially one out of proportion to the bulk of the body. The relief produced by such a rapid decrease in weight is but too often of a delusive nature, for while the patient and his respiratory function are rendered temporarily more comfortable by the disappearance of fat from the bowels and thorax, general debility is sure to supervene very soon, and often violent dyspnœa as a result of the loss which the heart muscle sustains simultaneously with the reduction of the fat; various disturbances of the circulation occur, and the fatty degeneration with a rise of temperature is often followed by myocarditis with all its serious consequences. Such a picture is one which was formerly but too often seen, and even to-day is not infrequently met with. What a marked difference is seen as the result of a dietetic-balneological-gymnastic treatment correctly carried out! It certainly requires more time, but the risk is so much less and the success so much greater. Had I space I might relate a long series of such cases. Many of them have been published either by myself or by physicians who have familiarized themselves with our method of treatment in Nauheim.

By this method of treatment we soon notice a marked change for the better in the patient, and I have often had occasion to point out this improvement to my colleagues. As indicative of the favorable effect of the treatment we find that the small pulse becomes of fuller volume, the arrhythmia disappears, and the elevations of the pulse diagram, showing the elasticity of the arterial wall, become more visible and frequent; the pressure of the pulse gets stronger; a tachycardia disappears, while not unfrequently we see a bradycardia give way to a normal frequency; the pale or yellowish complexion of the patient becomes of a ruddier hue; the sounds of the heart become louder; the dilatation, which is always present in cases of advanced fatty heart, gradually disappears; the ictus cordis, which could scarcely be felt, becomes more perceptible, the respiration freer and deeper, and the capability for physical exercise increases day by day, so that finally the patient can walk for hours without trouble, and even ascend slight elevations, and now it is when this amount of improvement has been achieved that he may safely be allowed to make somewhat longer excursions in the mountains. It does not follow that because, by assiduous attention and constant care, and with the aid given by the frequent use of the thermometer, we have brought about such a favorable condition in our patient, the treatment can then be abandoned; on the contrary, we must impress upon him the necessity of his continuing for many months the same regimen of diet and exercise, and if he be of middle or of advanced age the danger of a relapse should not be lost sight of; in a younger person this danger is by no means so probable. I therefore generally advise the patient on his return home to continue for quite a while his gymnastics with resistance, for by so doing I am sure that most striking and enduring results are accomplished. One ought never to forget that in cases of fatty heart our chief aim should be to strengthen the cardiac muscle and to maintain its vigor. The latest researches in this field all go to prove the correctness of our views. The increased bulk of the heart is only due to its being covered by or partially made up of fat, while its muscular substance is inferior in quantity to that of a normal organ, as has been fully confirmed by the latest investigations of C. Hirsch; the quantity of the muscle of the heart is always in a direct proportion to that of the whole body. Hence the more we increase the muscular strength of the individual *in toto*, the more we strengthen his cardiac muscle. That such a satisfactory result may be readily obtained by our balneological and gymnastic method, I have already attested in my published cases. Of these many were cases of fatty heart under my care at Nauheim, and their daily improvement and ultimate recovery I was able to demonstrate to a large number of physicians stopping in that town, some for study and some for their health.

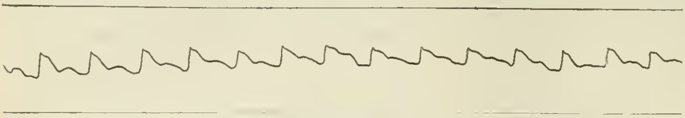

Fig. 3.—After an Effervescent Bath (Sprudelbad) of Spring No. VII., of 86° F. and ten minutes' duration.

As an ocular demonstration of the beneficial effect of bathing and of gymnastic exercise I give here without further details the diagrams of the pulse and measurements of its pressure, taken from two patients. Figs. 1 to 3 refer to a wine merchant, thirty-three years of age, whose height was 1.70 metres, but who weighed two hundred and twenty German pounds. He suffered greatly from fatigue and from dyspnœa even in a state of rest. Frequency of the pulse after a long repose, 110; pressure of pulse, 95 mm. Hg.; respiration, 26.

Fig. 2 shows the effects of gymnastic exercises of twenty minutes' duration resorted to immediately after the first medical examination. The patient felt relief in breathing. The pulse was fuller and much less compressible; frequency reduced to 100–98; pressure, 110 mm. Hg.; respiration, 21.

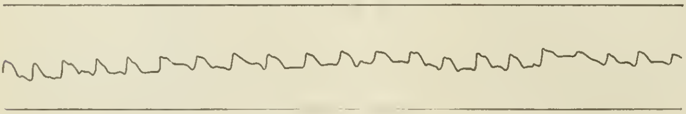

Fig. 4.—Before Treatment.

Fig. 3 shows the effect of an effervescent bath (Sprudelbad) of spring No. VII., of 86° F. temperature and ten minutes' duration, which was taken immediately after the above-mentioned exercises. The respiration was lowered to 18; pressure of the pulse rose to 115 mm. Hg. Its frequency went down to 94. After a treatment of six weeks the patient, although he had lost only six pounds in weight, was perfectly free from all his complaints.

Fig. 4 is taken from a lady from New York, Mrs. S——, forty-seven years of age, of middling stature; weight one hundred and eighty-two pounds. Pulsus inæqualis; frequency, 132; pressure of pulse, 95 mm. Hg. The patient took a cure of five weeks' duration in Nauheim, when in order to avoid the season of extreme summer heat she spent an interval of two weeks among the mountains, and then resumed the course of treatment in Nauheim for another three weeks. She took altogether thirty-four baths, and once or twice daily went through with the gymnastic movements with moderate resistance. The reduction of the patient's weight amounted to only four pounds, but while before treatment her breathing had been short she could now walk for hours without trouble. The anæmia had left her, and she felt perfectly sound and well.

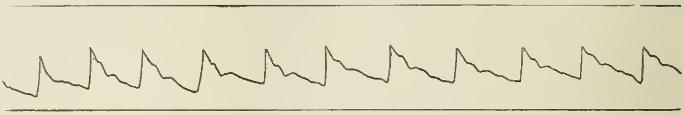

Fig. 5.—After Treatment.

Fig. 5 shown clearly the change of the pulse; frequency, 72; pressure of the pulse, 130 mm. Hg.

ROUND ULCER OF THE DUODENUM.

By PERCIVAL R. BOLTON, M.D.,

INSTRUCTOR IN SURGERY, CORNELL UNIVERSITY.

The great rarity[1] of ulcer of the duodenum, in New York at least, has led me to think that a review of this subject and the report of several cases which have been admitted to the Hudson Street Hospital, four of them in the care of Dr. L. A. Stimson and one in my own, would not be without interest.

Case I.—Man, aged thirty-five years, a United States mail agent, a hard drinker. Eight hours before admission he developed very severe abdominal pain. There was no vomiting. On admission, the abdominal wall was tense; there was no distention; there was tenderness over the region of the gall bladder. The temperature was normal; the pulse 90. The temperature rose, and the tenderness became general; there was no distention. The liver dulness disappeared. The probable diagnosis was appendicitis. Twenty hours after the first symptom the abdomen was opened over the appendix, and a large amount of greenish-brown fluid was evacuated. The appendix was normal. There was a well-marked peritonitis. The patient's general condition prevented any further search for the focus of infection. He did not rally, and died some hours later.

The autopsy record has been lost, but Dr. Fielding Taylor, who was house surgeon at the time, says that there was a well-developed peritonitis, and that a round ulcer of the posterior wall of the first part of the duodenum was found about two inches from the pylorus. Its base presented a minute perforation.

---

[1] Kinnicutt, 0.4 per cent. among thirty thousand autopsies.

Case II.—Man, aged twenty-eight years, sailor; a hard drinker. No previous diseases of significance were noted. Two days before admission, without assignable cause very severe abdominal pain developed. It was not, so far as could be learned, referred to any particular region of the abdomen, but was accompanied by vomiting. There is no note of the character of the vomitus. The same condition continued the next day, and on the third he was admitted to the hospital. At this time there were general distention and tenderness of the abdomen; but no localized tenderness and no loss of liver dulness. The temperature was 103° F.; respiration, 20; pulse, 120. No further diagnosis was possible than peritonitis of unknown origin. The abdomen was opened by a liberal median incision. The intestinal coils were everywhere matted by recent fibrin. There was little or no fluid free in the peritoneal cavity. The patient's condition did not warrant a protracted search for the source of infection, and after rapid irrigation and the introduction of drains he was returned to his bed. Death followed on the third day, or the sixth from the time of the initial pain.

The autopsy showed a general peritonitis. In the posterior wall of the third part of the duodenum there was a sharply lined ulcer 2.5 x 0.75 cm. in dimensions, perforating the gut and exposing the pancreas, which at this point was necrotic and infiltrated by pus, as was the subperitoneal tissue about the duodenum as far as the jejunum, from which region the peritonitis was judged to start. The mucous membrane of the duodenum and ileum was pigmented, and the solitary follicles of the latter were very prominent.

Case III.—Man, aged thirty-five years, brakeman; a hard drinker. He is said to have had a similar attack thirteen years ago, and typhoid fever three years ago. A short time prior to admission he developed severe, not localized abdominal pain, accompanied by vomiting. On admission, the abdominal wall was rigid; there was no distention, but very great, though not localized, tenderness. Temperature, 102° F. The symptoms gradually improved until the fourth day, when there developed the symptoms of a rapidly spreading peritonitis, which seemed most probably to have originated in the appendix. The abdomen was opened over the appendix in the usual way, and a quantity of yellowish, not offensive fluid evacuated. The appendix was found to be normal. A well-marked peritonitis was present. At this time the patient's general condition became such that no further investigation could be safely carried out, and after placing drains he was returned to bed. He did not rally, and died some hours afterward.

At the autopsy the peritoneal cavity was found to contain some ounces of sero-purulent fluid. The peritoneal surfaces were everywhere congested and covered with a thin layer of fibrin. The first portion of the duodenum was adherent to the under surface of the liver to left of the gall-bladder by recent fibrin, and presented a perforation 2 mm. in diameter. The superior wall just beyond the pylorus contained an ulcer with indurated walls, whose base was perforated as above described. There was a second old but superficial ulcer in the posterior wall just beyond the pylorus.

Case IV.—Man, aged twenty years, an Assyrian, single; a tailor. There was no note of alcoholism. Seven months ago he had an attack of illness characterized by pain in the region of the liver and vomiting, lasting two weeks. A few hours before admission he developed severe pain referred to the right side of the abdomen, and accompanied by vomiting. On admission, the abdominal walls were found to be rigid; there was general tenderness, perhaps a little more marked in the region of the appendix. There was no tumor. The temperature was 102° F.; respiration, 48; pulse, 118. The probable diagnosis was appendicitis. Twenty hours after the beginning of the attack the abdomen was opened by an incision over the appendix, and a quantity of watery fluid and odorless gas evacuated. An active peritonitis was present. The patient's general condition failed rapidly and compelled the abandonment of further procedures. Death followed in twenty-four hours.

On autopsy, the abdominal cavity contained several ounces of thin, offensive pus. There was a general peritonitis associated with considerable exudation of lymph. Immediately beyond the pylorus in the anterior wall of the duodenum was a round ulcer 1 cm. in diameter, whose edges were thickened and whose base presented a small perforation.

Case V.—Man, aged forty-five years, German, married; clerk. The family history was good. He was a moderate drinker. A similar attack is said to have occurred four years ago. Personal history otherwise was negative. The patient was perfectly well until six hours before admission, when he was seized with severe pain referred to the right iliac region, which gradually increased in severity, becoming general, but most intense in the right side of the abdomen. On admission, the abdominal wall was tense; there was no distention; tenderness was well marked over the appendix; there was no tumor; liver dulness was present. The temperature was 100° F.; respiration, 32; pulse, 104. At the time of operation, twenty-two hours after the onset of pain, the symptoms were the same except that distention was beginning to develop. The probable diagnosis was appendicitis. The abdomen was opened over the appendix, evacuating a considerable amount of turbid serum. A well-marked peritonitis with fibrinous exudate was present in the right half of the abdomen and iliac fossa, but the appendix, except for its peritoneal coat, was normal. Following up the ascending colon and its hepatic flexure the region of most intense peritonitis was found beneath the liver and about the duodenum, but no perforation of this part of the intestine could be recognized, though it was assumed to exist. Accordingly a large iodoform-gauze drain was carried from the region of the duodenum out through the abdominal wound, which had been extended up to the margin of the costal cartilages. The whole abdomen was repeatedly flushed, particularly the pelvis, where a large amount of fluid exudate was found, and ample drainage provided for. The patient rallied well and did fairly for several days; then he became septic, dying on the seventh day after operation.

The autopsy showed the following: In the regions of the wounds and in the iliac fossa the parietal peritoneum was adherent to the subjacent coils of intestine which were also adherent to one another. There was a moderate amount of puro-fibrinous exudate in the right iliac fossa and along the ascending colon. The omentum covered most of the coils of small intestine, and these showed only slight congestion and injection of the peritoneal coat. The pelvis and abdomen generally were perfectly free from fluid of any sort. There was no ulceration of the slightly thickened mucous membrane of the stomach. The pylorus was normal.

Immediately below the pylorus on the antero-superior surface of the duodenum was an old oval ulcer 1.5 cm. in length, its long axis being transverse, whose edges were thickened and rounded. The base of the ulcer was composed of peritoneum and presented a perforation 8 mm. in width. A depressed scar 1 cm. in diameter was located 2 cm. to the right of this ulcer. The rest of the duodenum was normal. The mucous membrane of the cæcum and ascending colon presented a number of grayish irregular patches of necrotic false membrane.

Lesions.—These cases illustrate fairly well some of the pathological features of the disease under discussion. In four of them the ulcer occurred in the first part of the duodenum within two inches of the pylorus, twice in the anterior wall, once in the posterior, and once in the superior. In one case the posterior wall of the third portion was the site of ulceration. In three of the cases the ulcers were single; in the other two there was in one the cicatrix of a previously healed ulcer in the anterior wall of the first part, and in the other superficial ulceration of the posterior wall of the first part.

The ulcers averaged a little more than 1 cm. in width, and perforation had occurred in all; three times into the general cavity, once behind the peritoneum, once toward the under surface of the liver to which the duodenum was adherent. In all five a spreading or a generalized peritonitis was present.

Of Collin's[1] group of 262 cases, in 242, or 92.3 per cent., the ulcer was found within 4 cm. of the pylorus, in 10 in the descending portion within 10 cm. of the pylorus, and in 6 cases in the third portion. Of 119 cases in which the ulcer occurred in the first portion of the duodenum, in 68 the anterior wall was the site, in 3 the anterior superior, in 39 the posterior, in 6 the posterior superior, in 2 the posterior inferior, in 10 the superior, in 1 the inferior; of 8 ulcers of the second part 5 occurred in the internal wall, 2 in the posterior, and 1 in the external; of 4 ulcers of the third part, in 3 the anterior superior wall was affected, in 1 the posterior.

In number there is considerable variation. Among 233 cases, in 195 it was single, in 38 there were two or more. There is considerable variation in size and outline, but usually the ulcer is not large, involving but a small portion of the circumference of the gut; the base may be formed by the submucous, muscular, or peritoneal coats, and occasionally by the tissues of neighboring structures to which the duodenum may have become adherent. The margins and base of the ulcer are commonly very tough and dense, and show but feeble attempts at repair.

Perforation is stated by Collin to have occurred in 69 per cent. of his group of 262 cases, with a circumscribed or general peritonitis in 125 cases; in 38 perforation is said to have been prevented by adhesions to the pancreas, liver, or gall bladder, but the percentage of perforations is placed at a lower figure by other writers, *e.g.*, as low as 42.8 per cent. by Chvostek.[2] This discrepancy depends, no doubt, upon the great uncertainty that must always practically attend the diagnosis of duodenal ulcer.

The circumscribed peritonitis which sometimes follows perforation may result in accumulations of pus beneath the diaphragm, subphrenic abscess (Maydl), or in fistulæ between the duodenum and the surface of the abdominal wall, the colon, or gall bladder; or fatal erosion of contiguous vessels may occur.[3]

As the effects of cicatrization Collin notes, among thirty-nine cases, dilatation of the stomach or duodenum, stenosis of the duodenum, obliteration or dilatation of the common bile duct, stenosis of the orifice common to the common bile and pancreatic ducts.

Etiology.—By most pathologists round ulcers of the duodenum are regarded as identical with those of the stomach in general characters, and are supposed to be due to the action of gastric juice upon the mucous membrane, one or other, or both, being abnormal. This explanation depends for its basis upon the fact that the vast majority of duodenal ulcers are found in the first and second portions, above the entrance of the pancreatic duct, and therefore where the mucous membrane is exposed to the acid gastric contents prior to their neutralization by the alkaline pancreatic juice and bile.

Sex, for some reason, seems to be an important etiological factor. Collin states that 79 per cent. of the cases of duodenal ulcer occur in males; the greater frequency in males being due to the more habitual use of alcohol by that sex.[1]

As to the influence of age, Collin arranges 297 cases as follows:

Between	birth	and	10	years	42
"	11	"	20	"	24
"	21	"	30	"	43
"	31	"	40	"	52
"	41	"	50	"	46
"	51	"	60	"	41
"	61	"	70	"	18
"	71	"	80	"	10
"	81	"	90	"	2
"	91	"	100	"	1

In this table are included 38 ulcers following burns and 3 following erysipelas, etc.

Symptoms.—It is indicative of the difficulty of diagnosticating the presence of duodenal ulcer that in the great majority of cases the lesion has not been recognized before perforation. Indeed it has been stated that diagnosis is impossible; but Boas[2] denies this and narrates the histories of several cases in which he was able to recognize the presence of the ulcer. He groups the symptoms under the following heads: 1. Sensitive points—correspond to seat of pain in parasternal line, 2 cm. below the gall bladder. There are numerous exceptions. 2. Vomiting. Vomiting, probably reflex, occurs after prolonged and severe pain; it is present in 17 per cent. of the cases. 3. Intestinal hemorrhage and hæmatemesis are present in one-third of the cases in marked degree. The loss of blood may be so great as to cause symptoms of collapse or even to be fatal. Repeated intestinal hemorrhages along with the other symptoms of the ulcer are characteristic. 4. Composition of the stomach contents. Observations have differed so much that at present no value is to be attached to hyper- or subacidity. 5. Urine, negative. 6. Jaundice is not significant.

Perforation of the duodenum at the site of ulceration, however, marks the beginning of a sequence of symptoms of severe character which vary somewhat, depending upon the seat of the perforation, the rapidity of the escape of intestinal contents, and development of adhesions. The first symptom noted has usually been severe pain referred at times to the region of the duodenum, to the upper part of the abdomen, or not localized at all. Vomiting usually promptly follows the onset of pain.

In some of the reported cases shock was said to have been present at first,[3] but in none of the Hudson Street cases was this at all conspicuous, and in the patient who was admitted very soon after the beginning of his symptoms none was present.

The next symptoms to appear are those of peritonitis. These are usually those of the severe and rapidly spreading type, and directly controvert the theory that infection by the contents of the upper parts of the intestine is less serious than by that lower down. Less often the peritonitis is circumscribed. In either case the inflammation begins in the right side of the abdomen. It thus simulates with great exactness the peritonitis which originates in appendicitis. Indeed the whole picture is that of appendicitis, and in many of the cases operated upon the probable diagnosis was appendicitis.

[3] Perry and Shaw: Guy's Hospital Reports, 1893, p. 266.

There are other lesions giving rise to peritonitis, with which it is readily possible to confound perforating ulcer of the duodenum, and of these ulcer of the stomach, pancreatitis, suppurations of the liver and biliary ducts occur to the mind at once. About the symptoms of the peritonitis itself there is nothing that is diagnostic, and the only really significant symptom, which may be but is not always present in intestinal perforations of whatever kind, is loss of liver dulness. When present, this is a symptom of great value, but its absence is by no means conclusive.

Course; Prognosis.—What proportion of ulcers of the duodenum cicatrize spontaneously is difficult to say; a considerable number do so, as the tables of Collin[1] show, where the effects of thirty-nine cicatrized ulcers are recorded. It would seem equally difficult to estimate the duration of the ulceration, and I know of no figures that furnish any information on this point, and I question the value of attempting any computation in this direction through the close relation this ulcer bears to that of the stomach. It is probable that a given ulcer will perforate the wall of the intestine sooner or later, and in that event the prognosis is always most grave; the peritonitis so produced is most likely to become a generalized one and terminate fatally; a circumscribed peritonitis with rupture of the abscess into a neighboring viscus or through the abdominal wall is the rarest event, and is never to be counted upon. Nor have any considerable proportion of patients submitted to operation after perforation has occurred survived. Of twenty cases of perforation treated by operative measures collected by Darras,[2] seventeen patients died and three only recovered. But here again, as in almost all cases of perforative peritonitis, the result of operative interference depends in no small measure upon the period at which it is undertaken.

Treatment.—Ulcer of the duodenum is not likely to come into the hands of the surgeon for treatment before perforation has occurred, and it is, therefore, this phase of the lesion that will be considered here. In rare instances the shock consequent upon perforation may be very severe, and even fatal,[3] but, as a rule, it is not very conspicuous, as might be inferred from the slow escape of intestinal contents through a minute opening. If at all marked or severe, it goes without saying that shock must be energetically combated before any extensive operative procedure may be undertaken. Nevertheless interference must not be too long delayed, and I think no one will dispute the statement that in the presence of a spreading peritonitis there is far less danger to life in incision of the abdominal wall than in delay. Hence I believe that the earliest possible moment is the time for operation.

The problem presented resolves itself into two factors: (1) the treatment of the duodenal ulcer; (2) the treatment of the peritonitis.

In a certain proportion of cases circumstances, notably a rapid decline in the patient's general condition, or failure to discover the perforation, may render any direct attack upon the ulcerated duodenum impossible, and make drainage by carrying a gauze tampon from the site of perforation out through the abdominal wall the only plan available. But this should be regarded as only tentative, and a more rational scheme carried out as soon as may be.

Various operative procedures have been practised at times upon the ulcerated and perforated wall of the duodenum. Closure of the perforation by sero-serous sutures seems hardly sufficient to achieve more than obliteration of the perforation; the ulcer itself persists, and even if cicatrization occurs there is no provision against the consequent distortion or narrowing of the gut. Resection of the segment of the duodenum which bears the ulcer is objectionable also. It is applicable only in the first part of the duodenum and in the presence of a single ulcer or at least multiple ulcers over only a very limited longitudinal extent of intestine, and finally it seems unnecessary except when a great part of the circumference of the duodenal mucous membrane is involved. Gastro-enterostomy, except to supplement excision of so much of the duodenum that enterorrhaphy cannot be practised, has nothing to recommend it.

The most eligible plan of treatment consists in excision of the ulcer. This may be done in almost any part of the duodenum except the entrance of the pancreatic duct, and is not at all difficult in the first portions of the duodenum where ulceration is most apt to occur. The excision need not go very wide of the ulcer, but must be closed by Czerny-Lembert sutures, as in pyloroplasty, so that the suture line lies at right angles to the long axis of the gut.

The second factor in the problem, the treatment of the peritonitis, will depend in a measure upon whether the inflammation is localized, spreading, or general. For a peritonitis well circumscribed by adhesions nothing is necessary beyond sponging out the pus present and supplying adequate gauze drainage. For a more extensive peritonitis, and one that is spreading, it is doubtful how much and how little had best be done. It is the practice of some surgeons to expose the inflamed areas of peritoneum by eviscerating the patient, and to remove all of the adherent flakes of lymph, to sluice the peritoneum with salt solution, and then to return the intestine. Others do not allow the intestine to prolapse at all, but repeatedly flood the peritoneum with salt solution. Afterward in either plan the peritoneal cavity is sponged dry or left full of salt solution.

Again, by many operators the freest possible drainage is provided by carrying gauze or tubes to all of the conventional drainage areas of the peritoneum, making additional incisions through the abdominal wall if they are needed. On the other hand, the free use of drains is sometimes regarded as dangerous and as likely to afford routes of infection that in the absence of drains would not exist.

Patients recover at times from septic peritonitis treated in any of these ways, so that at present no very definite rules can be formulated.

I myself am inclined at present to the opinion that no great advantage is gained in the treatment of peritonitis by eviscerating the patient and submitting the already inflamed peritoneum to the prolonged exposure of manipulation necessary to remove adherent flakes of fibrinous exudate. On the contrary, I feel confident that by this proceeding shock is substantially increased without any compensating advantage, for the same removal of fibrin may be as well accomplished by passing the intestine beneath the wound; and it is certain that so far as the removal of fluid exudate is concerned this can be just as thoroughly done by carrying large quantities of salt solution through the Chamberlain tube to all parts of the peritoneal cavity; nor should one hesitate to break down adhesions for this purpose. Such irrigation, however, must be carried on until the overflowing fluid returns clear. Many times in the course of irrigations made in this way I have noted that marked improvement in the pulse occurred. After this irrigation the peritoneum should be sponged fairly dry; there is perhaps some advantage in leaving a quantity of salt solution, but an excess quickly finds its way out into the dressings.

As to the use of drains, no doubt a strip of gauze should lead down to the point of infection, and I habitually also drain in this way areas of peritoneum inflamed to the degree of producing a fibrinous exudate, but I have not found it necessary to drain regions which have simply been the repositories of turbid serum and which have not advanced beyond the appearance of pretty active injection.

THE PROPHYLAXIS AND TREATMENT OF GONORRHŒA BY METHYLENE BLUE.

By JOSEPH ALAN O'NEILL, M.D.,

NEW YORK.

Methylene blue administered internally will cure gonorrhœa in from four to seven days. To the diplococcus, which is the specific cause of this disease, it is especially fatal. The pyogenic bacteria that make gonorrhœa a mixed infection succumb very promptly to this germicide.

It is best given in gelatin capsules in one-grain doses three or four times a day. After the fourth day the dose may be reduced to twice a day. Given alone it sometimes causes irritation of the neck of the bladder, but when combined with oil of nutmeg there is no trouble of this kind. Oil of sandalwood is a desirable adjuvant because of its diuretic action and also on account of its sedative effect upon inflamed mucous membrane.

For several years methylene blue has been used in solutions varying in strength from 1 : 1,000 to 1 : 100 for direct irrigation of the urethra in acute gonorrhœa. But conservative practitioners are so opposed to this method of treatment, and the staining-properties of the methylene blue are so pronounced, that for use in this way it has not become very popular. Recent observations show that, when given internally, it reappears unchanged in the urine within two hours. This, of course, simplifies the problem of cleanly and complete urethral irrigation. By giving four one-grain doses of methylene blue daily there is always enough of it in the urine to kill all the germs it comes in contact with. This is irrigation "from above," irrigation not of the urethra alone, but of the entire urinary tract. By this method of irrigation there is no danger of forcing the infection into remote recesses of the genito-urinary organs. The urine impregnated with the methylene blue not only kills the germ, but also carries away its corpse.

Methylene blue is a coal-tar product, one of the aniline colors, and, like the other derivatives of the series, it lowers the blood pressure, diminishes the sensibility of the sensory nerves, and is, therefore, an antipyretic and an analgesic. In large or long-continued doses it causes vomiting, vesical tenesmus, and diarrhœa. Piotrowski reports ephemeral albuminuria, cephalalgia, nausea, and malaise from the exhibition of from one to three grains. These results are not confirmed by other observers; hence it is believed that he used impure drugs, possibly methyl blue.

I have seen troublesome gastric symptoms follow the administration of the methylene blue of the shops, but with the following formula put up for me in elastic capsules I have had uniformly satisfactory results: ℞ Methylene blue, gr. i.; oil of nutmeg, gtt. i.; oil of sandalwood, gtt. ii. I never continue the use of the above formula for more than ten days without intermission, and while giving it I instruct the patient to drink freely of water.

The recent widespread interest in methylene blue as a cure for gonorrhœa probably had its beginning in the address of Prof. Austin Flint, delivered before the New York State Medical Association in May, 1895, when he as president opened the eleventh annual meeting of that body. In the course of his remarks Dr. Flint said:

"In a few cases of gonorrhœa that were incidental to other diseases in the medical wards of Bellevue Hospital, I used methylene blue alone internally with great success. . . . In two of my recorded cases the results were truly remarkable. The first case was that of a man, thirty-five years of age, with moderate but characteristic discharge, which had existed for two or three days. He was put upon methylene blue, gr. iss. three times daily, and had no other treatment. The next day the discharge was very much diminished and the ardor urinæ had disappeared. I saw the patient again on the ninth day, and he was perfectly well. He stated that the discharge had ceased on the fourth day.

"The second case was that of a man, fifty years of age, with his first attack, who was seen by me the first day. In this case the gonococcus was discovered in the discharge. The patient took gr. ii. of methylene blue three times daily for three days, and twice daily for four days. There was a great diminution of the discharge on the first day, and on the seventh the patient was entirely well."

My results with this agent, while not so brilliant as those reported by Dr. Flint, have nevertheless been very satisfactory. In no case have I found it necessary to continue treatment for more than ten days. I have seen the thick, purulent discharge reduced in twenty-four hours to a thin, colorless mucus. This serous exudate would seem to me a necessary aftermath of any acute ulceration. Denude mucous membrane in the urethra or anywhere else, and there is bound to be some oozing of serum until the abrasion is healed. The mission of the methylene blue is accomplished when it has destroyed the bacteria of suppuration. This it does within a remarkably short time. It seems to have a specially deadly effect upon the gonococcus; and this leads me again to quote Dr. Flint, who, in closing his address, said:

"It is a reasonable scientific proposition that methylene blue would probably act as a prophylactic against gonorrhœal infection in impure intercourse."

For obvious reasons positive results from such preventive treatment are not obtainable; still it is so logical that it seems the proper treatment to advise for any patient who may need it. The physician who by this advice prevents the development of a single case of gonorrhœa really deserves his title—doctor.

Against such doctrine the moralist may rise in his wrath and charge collusion against social purity; but after discussing this theme at length with a number of the best and ablest physicians in New York, I am satisfied that the profession is ready and willing to meet the charge. Gonorrhœa is a social vulture that preys upon trusting women and innocent babes, and the physician who with a full knowledge of its remote results fails to give prophylactic counsel is indeed a colleague of the sinner, a party to a sin that menaces society.

Contrast the distorted dream of the social purist with the increasing list of hysterectomies, ovariotomies, and other mutilating operations made necessary by ignorance of simple prophylactic principles. Witness the anguish of the young mother who sees her babe blinded for life by ophthalmia neonatorum—and then dare to tell the father that it might have been prevented, not by instilling a silver solution into the eye, but by giving him a little golden advice about his gonorrhœa.

The prevention of gonorrhœa is as legitimate and laudable as the prevention of smallpox. To tell a man who has been exposed that methylene blue may forestall the penalty of his impurity can no more be regarded as aiding immorality than could the statement that vaccination will prevent smallpox. To withhold this information will not in the least tend to clear the social atmosphere nor to advance the interests of morality.

Clinical Department.

URETERO-VAGINAL FISTULA; OPERATION; CURE.

By F. W. JOHNSON, M.D.,

VISITING GYNÆCOLOGIST TO THE CARNEY AND ST. ELIZABETH'S HOSPITALS, BOSTON, MASS.

L. H. N—— single, thirty-five years of age, presented herself January 31, 1898, with the following history: She had been flowing slightly every day for the past three months without pain. Previous to this she menstruated every four weeks. She has lost five pounds in weight. The flowing has been most profuse during the afternoon and night. Menstruation began at the age of twelve years, and was perfectly regular every four weeks until three months ago. She flows from five to seven days, and saturates eight to ten napkins. She has scarcely any pain. She has no leucorrhœa, no vesical symptoms, and no constipation. Her mother died at the age of seventy, of cancer. Her father died, aged forty years, of some "liver trouble." She has always been strong and well, working in a factory since she was eighteen years old.

Physical examination revealed a small fibroid on the posterior wall of the uterus. On February 5, 1898, the uterus was curetted in order to get a specimen for microscopical examination. The pathologist reported that a microscopical examination of the scrapings showed marked proliferation of atypical glands in places invading the muscular tissue; also numerous small areas of degenerated and proliferated epithelial cells. The diagnosis was adeno-carcinoma.

On February 8, 1898, a complete suprapubic hysterectomy was done. Before opening the abdomen the cervical canal was thoroughly cauterized and the cavity packed with sterile gauze, and the cervix separated from the vagina at the vault anteriorly, laterally, and posteriorly, with the cautery. The uterus with tubes and ovaries was sent to the pathologist, who reported as follows: "The uterus shows one or more characterstic intramural fibroids of small size, and near the internal os two cauliflower excrescences, the size of an English walnut. A microscopic examination shows adeno-carcinoma of the uterus, involving principally the fundus, but showing no evidence of disease of tubes or ovaries."

On the separation of the slough made by the cautery, part of the urine began to run away through the vagina; the other part was passed naturally. Except for the leakage, the convalescence was perfect. On making an examination I found what appeared to be a uretero-vaginal fistula.

After waiting nearly two years without any improvement in the leakage, she consented to an operation which I had proposed long ago. Having seen the fistula a great many times, I had made up my mind that the ureter had been divided throughout its whole diameter just where it entered the bladder. When the patient was lying down or sitting no urine escaped into the vagina. Her general health had not appreciably suffered, and owing to her scrupulous cleanliness the vagina was in a healthy condition.

I had made up my mind to do the operation described by Dr. Howard A. Kelly for ureteral fistula at the base of the bladder. On examining the patient when she was etherized for the operation, January 11, 1900, I found the fistula was in the lateral wall of the ureter. An oval denudation in the vaginal walls and in the ureteral walls around the opening was made similar to the denudation for a vesicovaginal fistula. The sides of the denudation were brought together by means of interrupted silver-wire sutures.

February 20, 1900: The operation was a success, and there has been no leakage of urine since it was done, and what is better, there is no evidence of a return of the adeno-carcinoma.

EPILEPTIFORM CONVULSIONS, FOLLOWING THE INTRANASAL APPLICATION OF COCAINE.

By SAMUEL KOHN, M.D.,

NEW YORK.

Although the varied manifestations of the toxicity of cocaine have become fairly familiar to the medical profession, cases just like the one about to be described are so rare as to deserve more than passing notice.

C. R——, aged forty-six years, a man of strong physique, weighing about one hundred and eighty pounds, commenced to bleed from the nose at 4 P.M., April 29, 1899; at 5:30 P.M. I was called. Blood was flowing freely from both nostrils, particularly from the left; considerable blood had found its way through the posterior nares, pharynx, and œsophagus into the stomach, as was evidenced by the vomiting.

The patient sat with his head inclined forward, his face looking into a wash-basin containing considerable blood; the countenance was pale, and the man was nervous and trembling. Leaving the question of diagnosis for later consideration, I applied my method for checking nosebleed, which is described in No. 23, vol. xlv., of the Medical Record. The patient was placed in a chair, in an upright position; all constricting bands about the neck, body, and limbs were loosened, and he was instructed to breathe through the widely opened mouth, as deeply and as rapidly as possible. The principle upon which this simple method depends for its efficacy is the enforced stoppage of all currents of air, voluntary and involuntary, through the nostrils, until the bleeding ceases. The object achieved is complete rest for the interior of the nose, which favors coagulation at the bleeding point; of course, blowing the nose is strictly interdicted.

Whatever blood drips from the nares is to be gently touched off with the absorbent cotton; the head is to be inclined forward somewhat to prevent the escape of blood into the pharynx, which causes continuous hawking and spitting, and sometimes vomiting. In this case the bleeding ceased within a few minutes, and I submitted the patient, whom I have known for years, to a closer examination, with the following result: There were no growths or hypertrophies in either nostril; there was an erosion on the floor of the left nostril about the size of a small lentil, due probably to the patient's habit of picking the nose; the profuse bleeding from this slight trauma was explained by the full-blooded habit of the patient. The man had never been sick with any serious ailment, although he was a sufferer from rheumatic twinges now and then; he had been for years a steady but moderate imbiber of alcoholic stimulants; the heart sounds are unusually strong; no valvular lesions are apparent, so far as I could make out. The urine is free from albumin and sugar. These particulars are all thus detailed, because of the extraordinary effect upon the patient of a small quantity of cocaine applied externally, to be described presently. The cardiac hypertrophy and evident beginning arteriosclerosis were the predisposing causes of the profuse bleeding from the insignificant trauma.

At 8 P.M. I was again hurriedly summoned. The patient, finding that the bleeding had ceased for over an hour, had, contrary to my orders, washed out his nose with cold water, and, as is the habit of such patients, had violently blown his nose, to clear out all the clots; I found the hemorrhage as free as at first. The method just described was again employed, and, although it requiréd more time, was again successful in checking the bleeding.

Having another important case to see at the time, I asked my friend, Dr. M. S. Kakels, to remain with the patient until my return. At 10 P.M., on my return, the bleeding was effectually checked. On consulting with Dr. Kakels, however, we came to the conclusion, in view of the tendency to recurrence of the bleeding, to plug the nostrils loosely, in order to insure the patient against a fresh bleeding during the night. The introduction of Fraenkel's speculum, and the gentlest possible manipulation with the probe, started up a slight bleeding, to control which I determined to apply a ten-per-cent. solution of cocaine to the bleeding point in the floor of the left nostril. By means of an absorbent cotton applicator the cocaine solution was applied first to the left and then to the right nostril; in a minute or two a second application was made to the left nostril, whereupon the patient became deathly pale, somewhat cyanosed, the facial muscles commenced to twitch, general muscular relaxation set in, and he fell to the floor completely comatose; he was then seized with convulsions of the most marked epileptiform character, being thrown from one side to the other by the powerful clonic muscular contractions. The convulsive movements involved the right half of the body more than the left, and also the muscles of the face. There was some foaming at the mouth; the pupils were equally dilated. The pulse was feeble, 100, but perfectly regular, which feature encouraged us greatly. The convulsions continued for some five minutes without any sign of abatement, but they slowly became less marked, and at the end of about ten minutes ceased altogether.

The bleeding from the nose had ceased with the onset of the convulsions, and did not recur at any time. The patient remained very weak. The cause of this unusual effect of cocaine upon a powerful man, who had previously never had any illness worth mentioning, is undoubtedly the excitant effect of the drug on the nerve centres; although the cerebral anæmia, caused by the very considerable loss of blood and the patient's prolonged upright posture, may have contributed largely to the untoward effect.

Convulsions as a result of cocaine poisoning have been reported by Curgenven[1] after the ingestion of ten grains of the salt by the mouth. Garland[2] reports a death, in convulsions, forty minutes after the ingestion of fifteen grains of the salt. The smallest lethal dose thus far recorded is gr. $\frac{2}{3}$ by the mouth. So small a dose as gr. $\frac{1}{100}$, hypodermically, has produced faintness, pallor, tinnitus, etc. The instillation into the conjunctival sac of a four-per-cent. solution of cocaine, and applications to the gums, pharynx, larynx, and urethra, have caused similar symptoms. But the writer has been unable to find in the literature a single case reported of convulsions in an adult produced by the application of cocaine to the nasal mucous membrane by means of an applicator. Had a spray been employed it might have been said that a large quantity of cocaine had been absorbed by the nasal mucous membrane.

GUNSHOT WOUND OF THE KIDNEY.

By WILLIAM F. BARRY, M.D.,
WOONSOCKET, R. I.

ON July 25th, Mrs. B——, while engaged at her household duties, was shot by her husband. Two shots were fired, both taking effect—one in the right lumbar region, the other in the abdominal wall. The perpetrator of the deed continued his work, firing two shots into his wife's mother, and two more into his own head. The husband and mother-in-law died in a very short time. The wife fled from the room to the street, where she was picked up and brought to a neighbor's house. Dr. W. W. Browne, of Blackstone, Mass., was summoned, and immediately sent for the writer in consultation. On arrival I found the patient pale and profoundly shocked. The wound in the abdominal wall was giving little trouble, but the wound in the back was bleeding profusely. This was tightly packed with iodoform gauze until the hemorrhage ceased. Copious subcutaneous and rectal injections of saline solution with hypodermic use of strychnine, brandy, and nitroglycerin served to relieve the shock considerably. Fortunately the wound in the abdominal wall was only muscle deep, and the bullet was easily located at the opposite side. This canal was then irrigated and a wick of gauze placed in each end for drainage. It was decided to await events before more was done with the wound in the back. The following day the patient had rallied considerably, and was submitted to an x-ray examination. The bullet was located in the ilium of the right side.

Upon removing the bandages the following morning the dressings on the back were saturated with urine. There were, however, no signs of blood in the urine passed by the usual channel. It became necessary to change the dressings five and six times daily, and after the first day the urine passing through the bullet wound was not mixed with blood.

The patient was maintained in a well-nourished condition, and the sinus was kept well open to allow of free drainage of urine. It was evidently a case in which either the pelvis of the kidney or the ureter was injured. There were no symptoms pointing to injury of the intestine. The case was a very interesting one, as the patient continued to improve, and was very carefully watched by Dr. Browne and myself. There seemed to be about half the normal quantity excreted by the false passage and the remainder by the normal passage. Gradually the amount discharged upon the dressings diminished, while that passed from the bladder increased, until after about six weeks had elapsed the sinus closed entirely and has never given any concern to the patient since that time.

Mitral Stenosis.—Rummo says that (1) silent stenosis signifies a very slight lesion; (2) stenosis with presystolic murmur signifies a slight lesion; (3) stenosis with diasto-presystolic murmur signifies a serious lesion; (4) silent systolic stenosis signifies an extremely grave lesion, hyper-constriction, and very weak myocardium.—*La Riforma Medica*, February 7, 1900.

The Biological Action of the Essence of Bitter Orange Peel.—Francesco Valerio concludes from experimentation that this essence in heterodermatous animals produces paralysis by diminishing and finally abolishing the conductibility and the reflex powers of the spinal cord. In guinea-pigs, rabbits, dogs, and pigeons it produces convulsions by stimulation of the cortical motor centres of the brain, the bulbar centre being probably also involved.—*Giornale Internazionale delle Scienze Mediche*, December 31, 1899.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 Fifth Avenue.

New York, March 24, 1900.

PURE-FOOD LEGISLATION.

THE second pure-food bill to which we alluded last week, known as the "Brosius bill," provides in Section 1 that "the Secretary of Agriculture shall organize the chemical division of the Department of Agriculture into a bureau of chemistry," which, besides other duties, "shall also be charged with the inspection of food and drug products, as hereinafter provided in the act. The Secretary of Agriculture shall make necessary rules and regulations for carrying out the provisions of this act, under which the director of the bureau of chemistry," etc. There are several very serious objections to this first section, namely: it virtually places the responsibility of carrying out the act on a "bureau" instead of on the shoulders of one man who can be held accountable for the proper performance of his duties; second, it permits other executive departments to call on this "bureau" for such chemical work as may be required by them. Surely we believe a food bureau will have business enough of its own without undertaking any outside work. Third, it would appear to trespass on the present domain of the Treasury Department, so far as the inspection of foreign drugs is concerned; fourth, neither this section nor any portion of the proposed act states by whom this "director of the bureau of chemistry" shall be appointed. This is certainly a curious omission. Sections 2, 3, and 4 are administrative and appear to be right and proper. Section 5 reads "that the term 'drug' as used in this act shall include all medicines recognized in the United States Pharmacopœia and National Formulary, for internal or external use, and cosmetics," etc. We fail to understand why the "National Formulary," a work that we believe is simply a private business venture, is thus given such an authoritative position. And "cosmetics" too—surely that "bureau" will have its hands full. Section 6, if all reference to the "National Formulary" be omitted, is eminently satisfactory, with the single exception of the words "provided further, that no dealer shall be convicted under the provisions of this act when he is able to prove a written guarantee of purity," etc. We very much question the advisability of this provision; who is to guarantee the guarantor? Section 8 reads in part (italics our own), "That it shall be the duty of the Secretary of Agriculture to fix standards of food products when advisable, and to determine the *wholesomeness or unwholesomeness of preservatives and other substances which are or may be added to foods*, and to aid him in reaching just decisions in such matters he is authorized to call upon the *director or the bureau of chemistry and the chairman of committee on food standards of the Association of Official Agricultural Chemists*, and such physicians, not less than five, as the President of the United States shall select from the medical department of the army, the navy, and the United States Marine Hospital, and not less than five *experts*, to be selected by the Secretary of Agriculture by reason of their attainments in *physiological chemistry and hygiene*, to consider jointly the standards of all food products (within the meaning of this act), and to *study the effect* of *preservatives and other substances added to food products on the health of the consumer*," etc.

Referring more particularly to the portions of the section we have placed in italics, we earnestly inquire what there is in the education of a chemist or any expert in "physiological chemistry and hygiene" that qualifies him in any manner to judge of the wholesomeness or otherwise of "preservatives." If a person suffers in consequence of taking preservatives, he seeks relief not of the chemist but of the physician. The true test of the effect of "preservatives" is clinical experience. The chemist at best has but negative evidence, as the positive evidence when it exists would come only to the knowledge of the practising physician. An advertisement of one of the most commonly used preservatives reads as follows: "The preserving of meat demands modern methods. Wisdom is shown by selecting a Preservative Reliable and also absolutely Harmless." The use of this very preservative (in dairy products), however, is forbidden by State law and by ordinances of the health department of this city. Yet we have known a professor of physiological chemistry to state positively before one of the senate committees of this State that the preservative in question is absolutely harmless. He based his conclusions on some experiments he had made on dogs. If he had consulted the columns of this and other medical journals and well-known works of reference, he would perhaps have believed otherwise. We admire the assurance of the chemists, but we must protest against their acceptance as authorities on questions of this nature. The province of the chemist is to determine the nature and composition of bodies, not their effects for good or ill on the human system.

Section 13 provides that the expenses necessary to the carrying out of the various provisions of the act shall not exceed $100,000.

Comparing the "Babcock" and the "Brosius" bills, we unhesitatingly give preference to the former, if modified as suggested in our last issue. The Brosius bill, on the other hand, contains so much that is objectionable that it should be entirely recast if it seeks to carry out its ostensible purpose effectively.

The Utah State Medical Society.—The next annual meeting of this society will be held at Salt Lake City, on October 2 and 3, 1900.

THE SURGERY OF MALIGNANT NEOPLASMS OF THE LIVER.

It is only within the last twelve years that any serious and systematic attempts to operate upon malignant growths in the liver have been made, and the earlier cases were attacked in a rather tentative and hesitating way. The removal of a tumor in the liver has almost always been attempted in connection with operation for some condition of the gall bladder or ducts, and not as a primary operation. Three of the earliest cases (Bruns, Garré, 1888, Hochenegg, 1889) were of this character, and in two of them certainly the operative work consisted in the removal of a carcinomatous mass secondary to malignant disease in the gall bladder. Since these cases, the reported attempts to remove growths from the liver have rapidly increased in number, and we are gradually becoming able to arrange our knowledge and lay down certain rules of procedure.

The kinds of growth with which we must be prepared to deal are, pathologically considered, adenoma, carcinoma, and sarcoma, the last very rare if primary, and hopeless if secondary, and the other two very little better under the latter circumstances. Adenoma of the liver, though not essentially malignant, behaves like a malignant tumor, and as a primary growth is commoner than carcinoma, to which it is closely related, and with which it may be described. Carcinoma is very commonly secondary to growths in the stomach, pancreas, gall bladder, or more distant structures, and its prognosis is proportional to the site and extent of the primary growth. Of course cases are almost always seen too late to be in the least suitable for surgical intervention, though if the tumor was originally in the gall bladder there might occasionally be a chance for its removal with the secondary hepatic deposit. We shall therefore be safe in saying that the only malignant tumors of the liver which are ever likely to be considered as at all operable are some adenomata and a very few secondary carcinomatous deposits, with very rarely a primary carcinoma, in all of which a diagnosis of probability at least is made early. If the tumor is a secondary carcinoma, it is important that the secondary quality is not metastatic, but depends upon continuity of tissue. In the case of true metastasis there must have been wide dissemination of the infection, and deposits will not be limited to the immediate region of the primary mass, so that operative attack is obviously useless. Primary carcinoma of the liver is a rare disease, but may sometimes be amenable to operative treatment.

Keen has recently (1899) added to the literature of the subject the history of a very interesting case in which a fortunate combination of circumstances as to site and conformation made the extirpation of a large tumor a brilliant success. The operation was undertaken with the diagnosis somewhat in doubt, and it was only after opening the abdomen that the growth was seen to be a nodular mass involving practically the whole of the left lobe of the liver. There had been no jaundice, no intestinal symptoms, and, in fact, no reason except that of locality for suspecting the liver as the seat of the trouble. The whole mass was removed, partly by ligature and partly by slow cauterization with the Paquelin instrument, and it is stated that the hemorrhage was never alarming. The size of the wound in the liver was reduced as much as possible by drawing over the peritoneum, and packing was introduced down to the rest of the surface necessarily left raw. Recovery was rapid. Examination of the tumor showed it to be one of the forms of carcinoma, with many areas of necrosis in it, and the case seems to have been one of true primary carcinoma of the liver which came to operation before the lymphatics were involved, since these were reported uninfected at the time of the removal of the growth.

It is only in such cases in which there is distinct delimitation of the disease that we can hope to do anything of a radical nature, and it is also evident that as disease approaches the hilus it becomes more dangerous and less suitable to any operative treatment. The method of operation is really the only element in the question about which we can make any definite rules, for as regards diagnosis, local involvement, site of tumor, and prognosis, each case is a law to itself, and it is only when we have come to some sort of a decision upon all these points, either before or after the beginning of the operation, that we reach a stage where we can lay down general rules. Experience has shown pretty conclusively that the cautery and ligature alone or combined are the safest and quickest means of controlling bleeding from hepatic tissue, and that pressure with packing is a useful adjuvant. The cauterized wound in the liver should be treated by packing, and the abdominal cavity protected from contamination by the same means. All means of combating the effects of hemorrhage should be ready for immediate use, for it is never certain that we can avoid serious trouble in this regard. Widening experience will probably show that the adenoma is the most favorable for operation, and secondary carcinoma the least so; in fact, that the latter is practically never operable except in a very few cases in which the growth has started in the gall bladder or ducts and has extended to the liver by continuity of tissue. Furthermore, there is no prospect that any but growths in the superficial portions of the liver can be attacked successfully, even supposing that it were possible to make a diagnosis with reasonable certainty when the tumor lies very deep.

Bile from healthy liver tissue will not hurt the peritoneum, but from inflamed and infected gall ducts it will cause peritonitis.

The Mission of Gen. Leonard Wood.—In an appreciative note of the work of General Wood in Santiago, *The Lancet* ventures the prediction that "General Wood will regenerate Cuba in the same manner as the British have regenerated Jamaica, and that in the course of time yellow fever will be exterminated in the former island." We believe this is a safe prediction, if only the politicians will leave him in Cuba and not drag him away in order to make him a vice-presidential candidate this summer.

News of the Week.

Measles at Yale.—Many cases of measles have been reported among the Yale students since smallpox attacked a freshman at the Sheffield Scientific School. Nearly all these students have gone to their homes.

The Western Ophthalmologic and Otolaryngologic Association will hold its annual meeting in St. Louis on April 5, 6, and 7, 1900, under the presidency of Dr. W. Scheppegrell, of New Orleans.

The Association of American Physicians.—The fifteenth annual meeting of this society will be held in Washington, in connection with the triennial congress, on May 1st, 2d, and 3d, under the presidency of Dr. E. G. Janeway, of New York.

Quarantine against Bovine Tuberculosis.—Governor Stanly, of Kansas, has issued a proclamation declaring a quarantine which practically prohibits the importation of dairy cattle into that State. The quarantine was established at the request of the Live Stock Sanitary Commission in order to prevent the further introduction of tuberculosis into Kansas herds.

Dismissal of a Hospital Ship Captain.—The master of the hospital ship *Missouri* has been dismissed from the army transport service as a result of an investigation of charges made against him by the surgeon in charge of the vessel. The main charges were that the captain refused to recognize that the surgeon, who had the rank of major in the regular service, ranked him on the vessel, and that he talked with others against the latter during the voyage from New York to Manila.

A New Hospital in Brooklyn.—The old Kent mansion, at Second Avenue and Sixtieth Street, Brooklyn, will soon be occupied by the new Bay Ridge Hospital, Dispensary, and Training-School for Nurses. The building has been given by Mr. John Beet for use as a hospital for five years, provided a sufficient sum is raised to cover the cost of equipment and part of the operating-expenses for the first year. It is expected that the hospital will be opened in June.

College of Physicians of Philadelphia.—At a stated meeting of the section on general medicine, held March 12th, Dr. Alfred Stengel presented a communication entitled "The Importance of Glycosuria as a Symptom." He pointed out that the urine normally contained traces of sugar, but that clinical significance was attached only to such amounts as were demonstrable by means of the ordinary tests. Glycosuria might occur apart from diabetes and might result from the ingestion of sugar or of starch in excessive amount. When, however, it was a symptom of diabetes it occurred independently of the quality and quantity of the food. Dr. David L. Edsall presented a communication entitled "The Relations of Diet to Diabetes." He pointed out the importance of determining in every case of diabetes the amount of carbohydrates that could be ingested without the development of glycosuria, as this constituted an important guide in treatment, for it had been shown that patients did worse when carbohydrates were wholly excluded from the diet than when they were permitted to have as much as they were capable of assimilating. When sugar appeared in the urine independently of the character of the food, the diet should, for a time at least, be restricted to fats and proteids. Dr. James Tyson read a paper entitled "The Treatment of Diabetes and its Complications." He attached first importance to the dietetic treatment and secondary consideration to the use of drugs. Among the latter arsenic and opiates were most useful, and particularly codeine and morphine. Alkaline mineral waters might be taken with advantage. For diabetic coma subcutaneous infusion of saline solution was indicated.

Philadelphia Hospital.—Dr. James M. Barton has resigned from the surgical staff and Dr. Samuel Wolfe from the medical staff. A third ophthalmologist has been added to the medical board, and Dr. Howard Forde Hansell has been elected to fill the vacancy.

Fiftieth Anniversary.—Dr. William B. Ulrich, of Chester, Pa., celebrated on March 15th the fiftieth anniversary of his entrance on medical practice. The event was commemorated by a reception to the Delaware County Medical Society.

Smallpox at Yale.—There have been four cases of smallpox among students of the Sheffield Scientific School during the past two weeks. None of the cases is serious. There has been a great exodus of students from New Haven, and those who remain of the associates of the sick men have been quarantined.

The Plague.—Major Taylor, surgeon in charge of the military hospital at Honolulu, reports under date of March 1st, that since the first outbreak in that city there have been sixty-four cases of plague with fifty-five deaths. He believes that the epidemic is over, though there may still be sporadic cases from time to time.

A Hospital for Contagious Eye Diseases.—A bill has been introduced into the State legislature providing for the establishment by the city of New York of a hospital for the treatment of contagious eye diseases. The institution is to be located in the borough of Manhattan, north of Fifty-ninth Street. The board of managers is to consist of Drs. John C. Lester, of Brooklyn, and John L. Adams, Peter A. Callan, and Thomas R. Pooley of New York, together with three physicians to be named by the mayor. The health department of the city is to furnish all food, medicines, and supplies.

Philadelphia County Medical Society. — At a stated meeting held March 14th, Dr. E. W. Holmes read a paper entitled "The Anatomy of Hanging," in which he made a comparison between hanging and strangulation, giving a description of the anatomical lesions produced by hanging, together with a consideration of the methods of judicial hangings and an analysis of the sensations of those hanged and resuscitated. Dr. S. Solis-Cohen, the retiring president, delivered an address entitled "Progress in Therapeutics." He dwelt upon the fact that disease and recovery represented a continuous process, and that the intervention of the therapeutist should be addressed to aiding and directing nature in her efforts to bring about the desired end.

A Congress for the Study of Tuberculosis will be held in Naples on April 25th–28th.

Dr. A. G. Wippen has been elected vice-president and treasurer, and Dr. William L. Ballenger professor of otology, rhinology, and laryngology in the Chicago Eye, Ear, Nose, and Throat College.

The State Sanatorium for Tuberculosis.—The Senate finance committee has reported favorably Senator G. A. Davis' bill appropriating $150,000 for the establishment of a State hospital in the Adirondacks for the cure of incipient tuberculosis.

South African War.—Sir Thomas Naghten Fitz-Gerald, the senior surgeon to the general hospital at Melbourne, Australia, has been appointed to an advisory post as surgeon with the British South African forces, and has left for the seat of war. Mr. Treves is returning to England, and Sir William MacCormac left Durban on March 10th for home.

Philadelphia Pediatric Society.—Dr. Miller presented a case of profound secondary anæmia in a girl two years old with symptoms also of rachitis. Dr. J. M. Swan reported a case of chronic valvular endocarditis following chorea. The patient was a girl, about ten years old, who had presented symptoms of arthritis, followed by an attack of chorea, and subsequently to which symptoms of endocarditis developed. Dr. J. H. McKee reported a case of a large sarcoma of the kidney, with operation and operative recovery. The child remained well for several weeks after the operation, but symptoms of recurrence soon appeared and finally terminated fatally several months after the operative interference. Dr. Alfred Hand, Jr., exhibited a sarcomatous kidney removed from a child, two years old, in which also temporary improvement followed the operation, although death resulted a short time later.

Alleged Hypnotism in the Courts.—A man has recently been convicted of murder in a Nebraska court, the principal witness against him being the wife of one of his victims, in order to be free to marry whom he is said to have killed his wife and the witness' husband. The case will be appealed on the ground that the accused was not permitted to enjoy his constitutional right to be confronted by his accusers, in that the principal witness, when testifying, was not required to face the accused, and that the court erred in permitting the witness to wear a heavy cloak and colored eyeglasses, purposely preventing the defendant looking her in the eye and thus forcing her to tell the truth. The attorney's defence to this plea will be that the allegations are true, and that while the constitutional right of the accused may have been violated technically, the step was necessary, as three physicians asserted that the woman was under the hypnotic influence of the prisoner to such an extent that she could not testify while facing him. This will afford a grand opportunity for the production of contradictory medical expert testimony.

A Twin-Bearing Family.—A circumstantial account is given in the New York *Times* of a remarkable occurrence in a New Jersey village recently. Three sisters living in the village gave birth on the same day to six children, three sets of twins, two pairs being boys and one girls. All were born between eight o'clock and midnight.

The Jefferson Medical College and Princeton.—A report has been current for some time that the Jefferson Medical College, of Philadelphia, was soon to become the medical department of Princeton University, but President Patton, of Princeton, has recently denied emphatically that any such union was contemplated.

A City Hospital for Tuberculosis.—Dr. Nelson H. Henry has introduced into the State Assembly a bill appropriating $350,000 for the purchase of a site and erection of a hospital for the treatment of pulmonary tuberculosis. Upon the completion of the hospital the New York City board of health is to have jurisdiction over it, and will prescribe the rules and regulations to govern the institution.

Seaside Hospital of the Brooklyn Children's Aid Society.—The Children's Aid Society of Brooklyn has received a gift of $10,000 from two women for the building of an infants' hospital and a beach pavilion as an extension to its other buildings used in the summer at Coney Island. The hospital will be reserved for cases of critical illness. The main floor will be divided into a number of rooms, so as to permit mothers to be with their sick children. The buildings will be completed in time for the summer season.

Improved Health Conditions in the Philippines.—Surgeon-General Sternberg has received a cablegram from Colonel Greenleaf, chief surgeon in the Philippines, saying that the total number of cases in the military hospitals in and around Manila March 12th was twelve hundred and eighty-seven. There has been a steady reduction in the number of cases under treatment at the hospitals since January 20th last, when they numbered twenty-five hundred and forty. The report, however, does not cover the sick in the hospitals of northern Luzon and at Iloilo. Reports received by mail from Manila are that the hospitals are in excellent condition, and that the bubonic plague has been fully checked, if not conquered.

Medical Courts of Honor in Prussia.—The institution of professional courts of honor is not a new one in Prussia. The army has its courts of honor and so has the legal profession, and on April 1st, the *British Medical Journal* says, "similar courts for the medical profession are to come into existence. The plan of organization is simple. In each district where there is an *Aerztekammer* (representative body of doctors) a court is to be established; it will consist of the president of that body, three of its members, and, in addition, a judge of one of the local courts. A central supreme court will act as court of appeal, and is to consist of (1) the director of the Prussian ministerial medical department, (2) four members of the central committee of the *Aerztekammern*, (3) two medical men specially elected by the king of Prussia. The courts are to exercise jurisdiction over all certified practitioners excepting medical officers of the army and navy and others for whom a state disciplinary board already exists. The scope of jurisdiction is defined by the new law as follows: 'Every medical man is bound to exercise his profession conscientiously, and by his behavior—both in his professional and in his private life—to show himself worthy of the respect which his profession demands. A medical practitioner who fails in the duties incumbent on him is subject to the infliction of a penalty by the court of honor. Political, scientific, and religious opinions or actions of a practitioner as such can never form the subject of proceedings in a court of honor.' The penalties which the court may inflict are: (1) Warning; (2) reprimand; (3) fine, not exceeding 3,000 marks (£150); (4) temporary or permanent withdrawal of the right to elect members of the *Aerztekammer* or to be elected a member."

A Medical Club Swindle.—A man has been arrested in Chicago for running a fake hospital association. He collected money from the members of the association, guaranteeing free hospital treatment for any who were sick. The dues were regularly collected, but when any member fell ill there was none but the public hospital to receive him.

Lucrative Divine Healing.—A man was recently arrested in Boston on a charge of fraudulent use of the mails, whose occupation was that of a "divine healer" by letter. He constituted in himself a faith-cure association which practised therapy by correspondence. It is stated that he employed forty girls in sorting and writing letters, giving what he called his "absent treatment," charging his distant patients $5 a month. It is alleged that his business has recently brought him in $30,000 a month.

Militant Advocates of Vaccination.—A Christian Scientist lectured recently in Victoria, B. C., on the "Failure and Iniquity of Vaccination," and his remarks were so outrageously slanderous and false that they aroused the ire of the anti-faith-healers in the audience, and a general mêlée ensued. When order was finally restored most of the men present bore marks of the fight, and several of the "scientists" acquired a sudden "belief" in epistaxis.

Another "Human Ostrich" has come to grief and the knife of the surgeon in Baltimore. According to the newspaper report of the operation, conducted at the Johns Hopkins Hospital, the following junk was removed from the man's stomach: Ninety-one nails, iron and wire, measuring from one to four inches in length; one pocketknife, seven knife blades, one about three-quarters of an inch wide; nine horseshoe nails, four inches long; eight screws, two and one-half inches long; eleven small pins, ordinary size; two screw-eyes; forty-nine tacks, some with very large heads; one small staple, twenty-five grains of ground glass, four brass watchchains, with catches and stays, and twelve and one-half feet of three-eighths-inch iron chain.

Mortality of Michigan during February.—In the *Michigan Monthly Bulletin of Vital Statistics* for February the secretary of State reports that 2,673 deaths occurred in Michigan during the month. This is 37 deaths more than during the preceding month, but over 1,100 less than during the same month of the preceding year. The death rate for the month was 14.5 per 1,000 of population, showing a considerable increase over January, whose rate was 13.0. There were 445 deaths of infants under one year of age, 210 deaths of children aged from one to four, inclusive, and 772 of persons aged sixty-five and over.

The Medical Society of the State of North Carolina will meet in Tarboro, Tuesday, May 22d, under the presidency of Dr. George W. Long, of Statesville. The board of medical examiners will meet Wednesday, May 16th, and will make their report before the adjournment of the society. The annual discussion will be held on the afternoon of the second day, Wednesday, May 23d, the subject being "The Continued Fevers of North Carolina," led by Dr. James M. Parrot, of Kingston. On Wednesday evening, May 23d, the annual essay will be read by Dr. R. H. Whitehead, of Chapel Hill, and the annual oration will be delivered by Dr. T. S. McMullen, of Hertford.

The Obligation of Caring for Sick Children.—A child of Christian Science parents died not long since in Detroit of diphtheria. Its only treatment consisted in assertions by healers that nothing was the matter. When some of the sane neighbors, realizing the danger to the community and cruelty to the child of neglecting a case of contagious but usually curable disease, sought to make an example of the guilty parents, they were rebuffed by the prosecuting attorney. This legal light, according to the newspaper accounts, said that there was nothing to be done, since no doctor had failed of his duty in reporting the case, and the relatives and healers, not being physicians, could not be charged with knowing and concealing the nature of the disease.

An Epidemic of Pneumonia.—A strange story of the practical extinction of a family by pneumonia is reported in the New York *Times* of March 17th. On Thursday of last week, it says, a farmer residing near Deckerstown, N. J., died of pneumonia. He was ninety years of age. Two hours after the funeral, on the following Saturday, an unmarried daughter, aged sixty-five years, died of the same disease. Another daughter lay seriously ill with pneumonia in an adjoining room, and she died last evening. A married daughter came to her father's home to care for the afflicted ones, and she is now ill with pneumonia, and has slight chances of recovery. A son, who has conducted the farm for several years, and his wife are both afflicted with the same malady at the family homestead.

Dr. William McNeill Whistler, a brother of the celebrated painter, died in London on February 27th, at the age of sixty-three years. He was a graduate of the medical department of the University of Pennsylvania in the class of 1860, and served during the civil war as surgeon in the Confederate Army. At the close of the war he went abroad and took the diplomas of M.R.C.S. and M.R.C.P. He practised in London, and was physician to the London Throat Hospital.

Dr. Otto Leichtenstern, of Cologne, died on February 28th, of influenzal pneumonia. He was born in 1845 at Ingolstadt. After teaching for a few years, subsequent to graduation in medicine, at the Universities of Munich and Tübingen, he went in 1879 to Cologne, where he succeeded Riegel as director of the medical division of the Bürger hospital. Dr. Leichtenstern was a well-known medical author, but the work which brought him his greatest renown was the discovery of the ankylostoma as a cause of anæmia in brick-makers.

Obituary Notes.—Dr. Benjamin S. Lewis, of Camden, N. J., died at Plainfield on March 10th, at the age of forty-three years. He had been a member of Camden city council and was a member of the board of health.

Dr. Orlando Fegley died at Allentown, Pa., on March 10th, at the age of sixty years. He was a graduate of the medical department of the University of Pennsylvania.

Dr. Justus Lessey died at Philadelphia on March 14th, at the age of eighty years, from angina pectoris. He was a graduate of Jefferson Medical College, but for a number of years has been incapacitated by loss of vision from the pursuit of his profession.

Dr. Samuel Hayes died at his home in Newark, N. J., on March 14th, of apoplexy, at the age of ninety-three years. He was a graduate in arts from Princeton in 1825, and for two years had enjoyed the distinction of being the oldest living graduate of that college. He was graduated in medciine from the Geneva Medical College in 1829. In 1895 he received the degree of LL.D. from Princeton. He was a corresponding member of the Munich Medical Society and of the Botanical Society of Ratisbon. He retired from practice many years ago, but was a trustee of Princeton University and president of a bank in Newark.

Dr. Albert B. Strong, of Chicago, died in the State Hospital at Kankakee on March 17th. Death was due to exhaustion, brought about by maniacal excitement, the attack being an acute recurrence of three similar afflictions. His mental collapse resulted from losses involved in the failure of a bank. Dr. Strong was born at Galesburg, O., and was a graduate in arts of Kenyon College. He served during the civil war in the Eighty-fifth Volunteer Infantry, and afterward took up the study of medicine, being graduated from the Rush Medical College in 1872. He was a member of the Chicago Medical Society, the Illinois State Medical Society, and the American Medical Association.

Dr. Adolph Callison died at his home in this city on March 16th, on his eighty-second birthday. He was born in Copenhagen, and was the son of Dr. Adolph Callison, a court physician to the king of Denmark. He studied at the universities of Copenhagen and Kiel and in Vienna, Berlin, and Paris. He came to this country about fifty years ago and established a private school. He had not practised medicine for many years.

Dr. Thomas B. Hood died at his home in Washington on March 15th, at the age of seventy-one years. He was born in Fairview, Ohio, and was graduated from the Medical Department of the Western Reserve University in the class of 1861. He began practice in Columbus, but soon after the beginning of the civil war he entered the army and served as a surgeon. Subsequently for eleven years he was medical referee of the Pension Office, and since 1885 had practised in Washington. He was a professor of diseases of the nervous system in the medical department of Howard University, and was also dean of the faculty.

Dr. Hans R. Hoffmann died at his home in Union Hill, N. J., on March 18th, of pneumonia, at the age of thirty-five years. He was a graduate in medicine of the University of Leipsic in 1889.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 15, 1900.

Steam in the Treatment of Chronic, Hyperplastic, and Senile Endometritis, Putrid Abortion, and Puerperal Sepsis.—F. W. Johnson reports thirty-one cases in which steam was used instead of curetting. It is introduced into the uterus, after dilatation of the cervix, by means of an ordinary steam throat atomizer, to which a hard-rubber tube, eight inches long, conically pointed at one end, is connected by soft-rubber tubing. The steam as it leaves the boiler is at 212° F., and is allowed to enter the uterus for thirty seconds, and for another thirty seconds after the removal of the uterine speculum. Excellent results are claimed.

Injuries about the Shoulder at Birth.—J. S. Stone says that true congenital dislocation of the shoulder—that is, defective development of the scapula and head of the humerus—is of extremely rare occurrence. True traumatic dislocation of the shoulder at birth or in early infancy is also of very rare occurrence. Obstetrical paralysis is due, probably almost invariably, to a stretching and in some cases a rupture of the two upper roots of the brachial plexus. It is usually recovered from entirely in the course of a few weeks or a few months. In persistent cases surgical intervention may be of value.

Instruction in Co-ordination in Tabes.—J. J. Putnam has a patient who has been taught to stand and walk and do various exercises, and, considering the difficulties to be overcome, has made good progress.

Muscular Dystrophy.—J. J. Putnam reports a case in which the disease began at the age of thirteen years, and has progressed ever since, the patient being now thirty years old.

Acromegaly.—G. L. Walton describes a typical case. He believes that there is a relation between this disease and lesion of the pituitary body, if the secretion of this gland is increased.

Rupture of Quadriceps Extensor Tendon.—J. C. Warren reports two cases, in both of which operation gave excellent recoveries, with perfect functioning of the extensor muscles of the thigh.

Fresh Fractured Patella Sutured with Catgut through the Periosteum.—J. C. Warren operated one hour after the injury. The patient walked alone, without crutches, in six weeks.

A Second Case of Chronic Cyanosis without Assignable Cause.—Richard C. Cabot reports a case, probably due to venous congestion, the cause of which is unknown.

Resection of a Portion of the Liver for Adeno-Carcinoma of the Cystic Duct.—J. C. Warren performed this operation with good results.

Idiopathic Dilatation of the Colon.—R. H. Fitz reports a case in a child, aged two years, evidently due to obstinate constipation.

Poliencephalitis, Superior and Inferior, with Acute Anterior Poliomyelitis.—E. W. Taylor reports such a case in a man, aged twenty-seven years.

Journal of American Med. Association, March 17, 1900.

The Physician as a Witness in Court.—William J. Herdman proposes the adoption of the following suggestions as a means to secure much-needed reform in the matter of expert testimony: (1) Experts should be appointed by the trial judge. (2) Their compensation should be a part of the court expenses. (3) They should have abundant opportunity to investigate the facts of the case, so far as they bear on the opinion they are expected to deliver. (4) That opinion should be given to the court in writing, signed and sworn to. (5) Any dissenting expert opinion must also be in writing, and state the grounds on which dissent is based. (6) Experts may be sworn as witnesses and cross-examined, but the cross-examination is not to extend beyond the limits of the subjects embodied in the opinion they have been asked to express.

The Nutritive Function of the Bronchial Arteries in Growth; Disease and Repair of Pulmonary Tissue.—D. Lichty says it is the bronchial artery circulating in the intercellular spaces of the lungs, apart from the vessels involved in the pneumonic process, that prevents a sweeping destruction of the lung tissue when injured or diseased. Post-mortem evidences show us that the lung far exceeds any other tissue in the body—not excepting the peritoneum—in its ability to overcome the effects of tuberculous inoculation. The author concludes that we must admit this is largely due to the systemic circuit of the obscure bronchial artery and its nutritional activity.

Some Points in Treatment of Severe Crush Injuries of the Extremities.—John Prentiss Lord deprecates the tendency to over-conservatism in these cases, in the dictation of a watching and waiting course, and emphasizes a general need for a more universal application of the principles of drainage. To these principles he says must be added the application of the best surgical methods for carrying off and maintaining the wound products aseptic. This may be accomplished by an abundant hygroscopic dressing, though in more severe cases the moist antiseptic dressing is more efficient.

Symptomatology, Diagnosis, and Treatment of Neoplasms of the Kidney.—Under the head of symptomatology, L. I. McArthur includes: (1) Tumor in the renal region; (2) hæmaturia; (3) pain; (4) cachexia. As aids in determining diagnosis he gives: (1) Study of the history; (2) examination of the urine; (3) palpation; (4) cystoscopy, ureteral catheterization, and exploration by sounds; (5) direct exploratory incision. For treatment he gives: (1) Puncture; (2) nephrotomy, or (3) nephrectomy, according to the indications.

Infantile Diseases from the Standpoint of Biology.—Joseph Clements, in summarizing, says that we may accept the dicta that disease is abnormal vital activity, and the cause may be from without or may arise independently within; that the cause does not necessarily determine the nature of the disease, but the response of the vital activities to the contact relation of the irritant or cause, whatever it be.

May Not Gonorrhœal Vulvo-Vaginitis be Acquired by Children Indirectly?—Charles O'Donovan concludes from observation of cases after admission to the hospital wards that it is quite possible for the infection to be carried from one child to another by means of toys or otherwise. In uncleanly families the infection may follow the use of towels or the transferring of clothing from an infected to an uninfected child.

Renal Calculi.—M. L. Harris says that practically all kidney stones may be considered of bacterial origin. So far as medical treatment is concerned, he knows of none except it be symptomatic. When the diagnosis is made the stone should be removed, and there is at present no way to do this except by operation. The author states the mortality for stone in the aseptic kidney as a little over three per cent.; in septic kidney, over ten per cent.

Pathology of Renal Neoplasms.—Daniel N. Eisendrath says that during the past ten years great progress has been made in the pathology of renal growths, although much still remains to be investigated in this field. To this end every tumor should be carefully described and subjected to microscopical examination.

Case of Hepatic Abscess Presenting Some Points of Interest.—In this case, reported by Hermann B. Gessner, the writer thinks the suppurative hepatitis may be traced back to a dysentery occurring six years earlier. As to treatment, analgesia was successfully produced by means of a ten-per-cent. solution of eucaine-B.

Gastrectomy.—W. S. Thorne reports one more case in which this rare operation was performed. The patient survived the operation forty hours, dying from shock.

Professional Education and Ethics.—This is a plea by A. E. Baldwin for the better ethical instruction of students in dentistry.

Treatment of Gunshot Wounds of the Abdomen; Some New Statistics.—By H. H. Grant. See Medical Record, vol. lvi., page 906.

The Grippe Exanthemata.—By Harriet E. Garrison. See Medical Record, vol. lvi., page 28.

New York Medical Journal, March 17, 1900.

Shock and its Surgical Significance.—J. H. Rishmiller holds that sensory-nerve irritation sufficiently powerful to produce exhaustion of the vasomotor centre causes a reflex paralysis, and consequently a dilatation of the vascular mechanism. There are two forms of shock, according as hebetude or excitement predominates. Shock may to a large degree be prevented by counter-irritation applied to the extremities. Brandy per os and morphine subcutaneously before operating are prophylactic. Treatment consists in stimulating the vascular system and the application of artificial heat to the body. In cases of profuse hemorrhage an infusion of decinormal saline solution is indicated.

Apomorphine as a Hypnotic.—C. J. Douglas advises the hypodermic administration of doses of gr. $\frac{1}{30}$, to be given when the patient is in bed and ready for sleep. Restful slumber comes on in from five to twenty-five minutes. Cumulative effect is denied, and the remedy can be regularly used. Both as a hypnotic and emetic the remedy is thoroughly neutralized when dissolved in a saturated solution of boric acid—a fact which the author has never seen mentioned in literature.

The So-Called X-Ray Burn.—J. Rudis-Jicinsky divides the injuries from the *x*-ray into superficial dermatitis, spasmodic vascular contraction followed by immediate relaxation and renewed nutrition of the cells following upon the preceding mortification, and sequelæ of an acute attack with more extensive tissue destruction. He believes that the future perfection of apparatus and shortened time of exposure will diminish the untoward effects of the rays.

Varicose Spinal Veins.—C. E. Coon relates the history of a man, aged fifty-eight years, who died of tuberculosis, and who had suffered during life from excruciating pains in the lower extremities. Autopsy showed at the junction of the dorsal and lumbar vertebræ an extensive varicose condition of the spinal veins, which was thought to have been the cause of the pains.

Extensive Thrombosis of the Lateral Sinus and Internal Jugular Vein following Acute Suppurative Otitis Media.—M. D. Lederman describes a case of this nature occurring in a girl aged nineteen. He indorses liberal incisions of the soft parts in surgery of the mastoid. In this case the internal jugular vein was ligated in its lower portion. Secondary periphlebitis occurred, but the patient finally recovered.

Tinea Favosa.—C. A. Kinch gives the history of the literature of this affection, with a general statement concerning its pathology, characteristics, and treatment.

The Sheldon Murder Trial; Résumé of the Expert Testimony for the State.—By W. S. Cheesman and A. H. Hamilton. A continued article.

The Administration of General Anæsthetics.—By C. A. Temple. A continued article.

Medical News, March 17, 1900.

Instruments and Apparatus Used in the Diagnosis and Treatment of Gastric and Intestinal Diseases.—H. W. Lincoln enumerates, with a brief description of each, these instruments: Stomach tube, stomach bucket, œsophageal probe, gastrodiaphane, intragastric bag fitted with intestinal intubator, gastrograph, gastroscope; *x*-rays, photography, intragastric spray, intragastric electrode, gyromele, and powder-blower. He adds that each instrument has its field in the diagnosis and treatment of gastric and intestinal diseases, but many gastrologists depend largely for therapeutic results upon the stomach tube and lavage apparatus. There is, however, no question that the spray, electrode, and powder-blower are productive of some of the very best results.

Case of Pulmonary Tuberculosis Successfully Treated by Drainage and Iodoform, with Apparent Recovery.—Alexander Hugh Ferguson describes a case of this nature in a colored man, twenty-seven years old. In inserting the dry iodoform powder into the diseased lung tissue, no pain whatever was felt; but as soon as sound tissue was encroached upon, pain and uncontrollable coughing occurred. The emulsion also caused pain and coughing.

The After-Treatment of Fractures and Dislocations.—D. N. Eisendrath emphasizes the advantages of hinged splints, especially for elbow, shoulder, and foot, believing in the efficacy of active motion by the patient himself. He approves of massage in dislocations and fractures after the dressings are removed. He also speaks of gymnastic apparatus for ankylosis of the elbow and shoulder.

Tympano-Mastoiditis.—Emdon Fritz defines this affection as an inflammatory process which involves the tympanic cavity and the mastoid portion of the temporal bone. He cites three instructive cases.

The Significance of Earache in Children.—By T. H. Halsted. See MEDICAL RECORD, vol. lvii., p. 207.

Philadelphia Medical Journal, March 17, 1900.

The Spontaneous Disappearance of Senile Cataract.—Walter L. Pyle divides cases of this sort into those due to (1) absorption after rupture of the capsule; (2) dislocation of the lens; (3) intracapsular resorption of the cortex and sinking of the nucleus below the axis of vision after degenerative changes of the Morganian type; (4) complete resorption of nucleus and cortex without history of rupture, dislocation, or degenerative changes; and (5) disappearance of incipient cataract without degenerative changes or marked difference in the refraction. He reports a case in class 4.

Connective-Tissue Tumors of the Abdominal Wall.—Albert L. Stavely discusses the fibroid and sarcomatous neoplasms of the abdominal wall, and reports a case of removal of a small fibromyxoma from the inguinal region.

Gangrene of the Tonsil.—Alexander C. Howe reports a case of this nature in a man, twenty-six years old. A cure was obtained by cutting away the dead tissue and applying peroxide of hydrogen and nitric acid.

Hairpin Removed from the Bladder through a No. 12 Kelly Cystoscope.—Hiram N. Vineberg reports this case. The hairpin had slipped in, according to the account of the patient, a young woman, during an effort to extract a retroversion pessary.

Peroneal Type of Progressive Muscular Atrophy.—Theodore Diller reports two cases of this condition occurring in a brother and sister, twenty and twenty-five years old respectively.

A Case of Tetanus Treated by Subdural Injections of Antitoxin, and Hypodermic Injections of Carbolic Acid.—By Ernest Laplace. See MEDICAL RECORD, vol. lvii., p. 192.

Selections from the Lane Lectures.—A portion of a lecture on diseases of the arteries, delivered by T. Clifford Allbutt at Cooper College in 1898.

Glosso-Labio-Laryngeal Paralysis.—Francis P. Morgan reports a case of bulbar paralysis in a man forty-seven years old.

British Medical Journal, March 3 and 10, 1900.

Myasthenia Gravis Pseudo-Paralytica.—Thomas Buzzard gives the histories of two patients affected with this disease, a man and a woman. In these cases the results obtained by electrical examination were of great interest and importance, and the term "myasthenic reaction" has been applied to the remarkable behavior of the muscles under electrical stimuli. This "myasthenic reaction" should be sufficient to prevent the mistaking of these cases for hysteria, an error of diagnosis often made, and a very serious one, as the prognosis in this disease is very grave and death often occurs rapidly. As to treatment the best results seem to be obtained by rest, removal from disturbing surroundings, and good food. Feeding by tube, which is often of service in bulbar paralysis of the ordinary type, should be avoided.

The Causes and Treatment of Movable Kidney.—C. Mansell Moullin says that the width of the lumbar recesses is one of the penalties which have followed the assumption of the erect attitude, and that taking that width into consideration the wonder is not that movable kidney occurs, but that it does not occur more often. It accounts completely for the peculiar clinical distribution of movable kidney. It is hereditary and common; present in women much more often than it is in men; and in women who have borne children more often than in those who have not. As to the treatment the author says the choice lies between wearing an abdominal belt and nephrorrhaphy, the former expedient, in his experience, only succeeding in the milder cases, when combined with massage and muscle-strengthening exercises.

The Eye Symptoms of Locomotor Ataxia.—C. O. Hawthorne concludes from a record of thirty cases: (1) That an optic-nerve atrophy, an ocular paralysis, or an Argyll-Robertson pupil may exist as an isolated symptom for a long time; (2) that any two may be associated, with an increased presumption that the process causing them is of the locomotor-ataxia order; (3) that any one of the three or a combination of two or all of them may exist in conjunction with more or less pronounced evidences of spinal disease; (4) that occasionally a case which commences with purely ocular symptoms may be seen to develop with comparative rapidity characteristic symptoms of the spinal lesion of locomotor ataxia.

A Case of Complete Inertia and Prolapsus Uteri.—A case reported by F. L. Pochin, who says that the accident is extremely rare and has been ascribed to traction on the cord, either by the midwife or as a result of the funis being twisted round the child's neck. In this case the patient had been very anæmic for a long time before delivery; there had been some trouble with the afterbirth, and the midwife had "pulled the cord a little." The writer detached the placenta, bathed the uterus with hot boiled water, and returned it to its normal position. The patient quickly improved under stimulating treatment, and the puerperium was comparatively uneventful.

Perforating Gastric Ulcer, with Notes of Two Successful Cases after Operation.—P. Rhys Griffiths reports these cases, and says that the operation for perforating ulcer may be very easy or may be very difficult, requiring great care and patience to render the holes water-tight. The openings in the anterior wall are generally fairly easy to close, but the openings in the posterior wall, which fortunately rarely occur, often present serious difficulties. Absolute cleanliness is the keynote of success. In one of the cases reported recovery was uninterrupted, the other developed a subphrenic abscess.

A Contribution to the Surgery of Perforated Gastric Ulcer.—A. B. Mitchell considers this subject with special reference to the results of operations in Ulster, where the total number of cases operated on have been fourteen, with seven recoveries. The author draws the deduction that a few cases of true perforating ulcers result in recovery without surgical aid, but that the chief factors in successful treatment are early diagnosis and early operation. When once the physician suspects symptoms of perforation there is not a moment to be lost.

A Contribution to the Study of the Pituitary Body.—In this preliminary communication, W. A. Osborne and Swale Vincent say that their investigations have been performed, as were those of other observers, with ox material, but that they used dogs and rabbits for the experiment animals. In the main their results have been confirmatory of those obtained by others, with the addition of some facts in regard to the histological, chemical, and comparative physiological aspects of the question.

Maniacal Excitement during an Attack of Influenza.—John H. Spitzly reports this case, in which the patient, a man twenty-five years old, suffered delirium of so violent nature that the employment of a male nurse was necessary to keep him from throwing himself from the window. This excitement continued for nearly a week in spite of narcotics, the application of ice to the neck and head, and frequent doses of gray powder. There was perfect recovery from all symptoms in three weeks.

Suicide in Scotland.—Sir John Sibbald concludes after an examination of the statistics on this subject that the alleged increase of suicide must be regarded as not proven. We must keep in mind, he holds, that a great change has taken place in public feeling in regard to this matter of late years; the belief that the act of suicide necessarily involves disgrace has much diminished, and efforts to conceal its occurrence have therefore decreased. The degree of efficiency of the registering machinery must also be kept in view.

Diphtheria, Parturition, Retained Membranes, and Influenza in the Mother; Diphtheria in the Infant.—R. H. Steen reports this case as being of interest owing to the association of confinement with diphtheria and influenza. Both mother and child made good recoveries after the administration of large doses of antitoxin. The child received a dose of 350 units when five days old, and 1,000 units the following day, but exhibited no ill effects.

Case of Tabes Dorsalis with Bulbar Symptoms.—George E. Rennie reports this case, which he considers exceptional because of the severity of the laryngeal paralysis and the involvement of the other bulbar centres. The involvement of the pharyngeal muscles was so extensive that nasal feeding became a necessity, and the dyspnœa was so great that tracheotomy had to be performed and a tube worn, until the patient finally died of a lobar pneumonia.

Experiments to Determine the Efficacy of the Different Constituents of Haffkine's Plague Prophylactic.—C. Balfour Stewart gives the results of experiments with rabbits. Haffkine, on theoretical grounds, thought that the addition of the supernatant fluid reduced the case mortality, and the results obtained by Stewart show experimental confirmation of this theory.

Gastro-Jejunostomy for Gastric Ulcer.—In this case, reported by W. Jones Greer, the patient had suffered for nearly ten years from symptoms of gastric ulcer. Scientific dieting and rectal feeding failed to effect more than transient amelioration of the symptoms. Operation was followed by a complete return to health, the patient having gained twenty-seven pounds in four months.

Retention of the Placenta for Nine Days.—Griffith Griffiths reports this case. Douches of sublimate solution (1 : 1,000) and the administration of ergot and quinine (the latter for the malarious condition) resulted in a gradually subsiding temperature, followed by perfect recovery.

A Case of Tetanus.—W. Murray reports a case of well-marked tetanus in a boy ten years old, who had been wounded in the foot by a stone, in which recovery followed treatment by antitetanic serum, in conjunction with chloral and bromide of potassium.

Supernumerary Nipple.—E. G. Salt reports a case in which there was a supernumerary nipple on the under surface of the right breast which was large enough for the child to suckle, and from which milk flowed freely.

Practical Observations on Cancer of the Breast.—The first of the Lettsomian lectures, by Sir William Banks. See Medical Record, vol. lvii., p. 510.

The Surgery of the Stomach.—Abstract of the first Hunterian lecture, by A. W. Mayo Robson. See Medical Record, vol. lvii., p. 510.

The Anatomy and Pathology of the Rarer Forms of Hernia.—By B. G. A. Moynihan. The second of the Arris and Gale lectures.

The Lancet, March 10, 1900.

Tuberculosis of the Kidney; its Etiology, Pathology, and Surgical Treatment.—D. Newman concludes a lengthy article. He finds the process more virulent in some parts of the genito-urinary tract than in others, the bladder, prostate, and epididymis being more resistant than the kidney. He has been able to collect statistics of 135 cases of operation for tuberculous kidney done during the last ten years as follows: Deaths, one month or less after operation: exhaustion, 2 cases; extension of tuberculosis, 2 cases; uræmia (42 per cent.), 11 cases; various accidents, 12 cases; deaths, total immediate, 27 cases. Operative mortality, 27 out of 135, or twenty per cent. Remote results: of 19 cases no record; of the remaining 89 cases, died in two to three months, 6 cases; died in four to nine months 7 cases—total, 13; immediate deaths, 27; number of deaths within nine months, 40. General mortality after operation, 40 out of 135, or 29.63 per cent. Survived one to eight years, 45 cases, or 33⅓ per cent. Prognosis good or improvement great in patients alive one to nine months after operation, 31. Total survivors and promising cases, 31 plus 45, making 76, or 76 out of 135, or 56.3 per cent.

The Surgery of the Stomach.—A. Mayo Robson discusses the operative treatment of gastric ulcer and of hemorrhage due thereto. From the statistics on the subject and from his personal experience he concludes that operative treatment in acute hemorrhage gives such a high rate of mortality—64.2 per cent. as compared with from five per cent. to ten per cent. in cases treated medically—that it is better in such cases to rely solely on medical means. But in repeated chronic hemorrhages the operation of gastro-enterostomy affords a reliable method of treatment, since it gives rest to the stomach and removes the hyperacidity of the gastric juice. When the ulceration is at the pylorus, where it so frequently leads to hypertrophy and stenosis, the operation relieves the symptoms and cures the disease.

Practical Observations on Cancer of the Breast.—W. M. Banks discusses the question of the increase in cancerous diseases with its accompanying death rate. The prevalence of the affection has increased more among men than among women. He is disposed to lay great stress on the "flesh-eating" theory as the cause of the increase, for the disease is not so prevalent among vegetable and rice eaters. Most of the sufferers are persons who are likely to eat and drink too abundantly and do not take enough exercise, persons who live well and do not work off their spare products. He indorses the statement that "cancer is eminently a disease of persons whose previous life has been healthy and whose nutritive vigor gives them otherwise a prospect of a long life."

Complete Ossiculectomy (Removal of Remains of Drumhead, Larger Ossicles, and External Attic Wall) in Chronic Otitis Media.—R. Lake analyzes fifty cases. Both sexes were alike affected. Forty-two patients were cured, while three had temporary relapses. Improvement in the hearing-power was noted in twenty-one. The right ear was affected in twenty-nine and the left ear in twenty-one. The average age of the patients was 22.4 years, and the average duration of the disease was thirteen years.

A Suggestion for a Method of Opening the Pericardial Sac, Founded on a Case of Purulent Pericarditis.—C. Ogle and H. Allingham advocate a three-inch incision from the costo-xiphoid angle outward along the lower edge of the seventh left cartilage through which access is had to the pericardial sac, which can then be opened at its lowest part in front. The procedure has been demonstrated on the cadaver, but has not yet been tried on the living subject.

A Case of Gunshot Wound of the Abdomen with Injury to the Intestine; Recovery without Operation.—The patient was one of the soldiers engaged at the battle of Elandslaagte in South Africa, and came under the care of C. Reissman, a civil surgeon at Cape Town.

A Case of Rupture of the Brachial Plexus.—P. Stewart and M. Collier report the case, which occurred as the result of a fall in a man aged thirty-three years. The subsequent history showed that the patient had probably fallen during an epileptic fit.

On the Application of Electricity in Medical and Surgical Practice.—H. L. Jones describes the various forms of apparatus for electrical application.

The Sanitary Condition of the Irish National Schools.—By A. Roche.

Deutsche med. Wochenschrift, March 1 and 8, 1900.

Active Dilatation of the Heart.—Hans Herz discusses in its various aspects the dilatation of the heart resulting from an active alteration (not diminution) of tone of the cardiac muscle—hyperdiastole, described by O. Rosenbach in 1897. The condition occurs physiologically during active exercise, through the action of hot baths, sometimes in pregnancy, and during digestion. Pathologically it is seen in extreme nervous states, as a result of sexual excess, and in certain morbid conditions. It is very common in young persons of the working classes, say between fourteen and nineteen years of age, and is induced by rapid growth, physical labor, and the disturbances due to puberty. In later life the two conditions in which active dilatation of the heart most commonly occurs are obesity and abdominal plethora. The prognosis is usually favorable if the condition is recognized, but depends upon a prompt removal of the cause, in the effort to accomplish which the proper treatment consists.

A Piece of Bone in the Lung for Four Years.—Gustav Killian reports the case of a man, forty-two years old, who inhaled a splinter of bone. He suffered from a very severe and long-continued attack of coughing with bloody expectoration and a sticking pain in the chest. After this signs of pulmonary trouble appeared and continued with varying intensity for four years, during which time he consulted ten general practitioners, six specialists, and sought relief in seven hospitals and clinics in vain. The writer finally succeeded in extracting the foreign body by means of the bronchoscope and a tracheal forceps. The chip of bone measured 15 mm. in length, 11 mm. in width, and from 1 to 4 mm. in thickness (three-fifths, two-fifths, and one-twenty-fifth to one-sixth inch).

Simultaneous Extra- and Intra-Uterine Pregnancy.—Hermes reports the case of a woman, thirty years old, who had had three children born at term and five miscarriages. She had menstruated last in July. In September she was operated upon for extra-uterine pregnancy, the product being the size of an orange and connected with the left tube. The uterus was slightly enlarged and anteflexed. The woman made a good recovery, but as the uterus was apparently growing larger she was instructed to report regularly after leaving the hospital. This proved to be a normal pregnancy, and the woman was delivered of a full-term child in April.

Ophthalmoscopic Findings in Leprosy.—E. v. Düring and Trantas report ten cases of leprosy in which they found chorio-retinitic changes of a specific character, but in several instances these were very slightly pronounced. It is probable that these changes were present in some other cases in which a clouding of the media prevented a view of the fundus. These changes were associated very frequently with other lesions, such as iritis, cyclitis, and sclero-corneal lepromata. These lesions of the fundus are never seen in syringomyelia, and their presence is therefore of value in the diagnosis between this affection and leprosy.

A New Method in Physical Examination.—Eduard Weisz has noted a bulging of the intercostal spaces during phonation (counting), which he attributes to the pressing outward of the lung tissue. The bulging is not present over the spleen and liver, so that the lung marks out its own limits. The sign is absent also over a large pleural effusion. The patient is best examined while lying down, the chest being illuminated by daylight admitted from one side. Such words as "cat," "kilt," and "day" are among the best for phonation for this purpose.

Splitting of the Kidney.—Egbert Braatz reports the case of a woman, thirty years old, who suffered severe pain in the right kidney. An exploratory incision was made into the kidney but nothing abnormal was found. The pain disappeared for three years, then returned in great severity. The kidney was now extirpated, and examination showed a cheesy tuberculous abscess at the upper pole of the organ, and a healed tuberculous focus at the lower pole. Doubtless the latter had been the cause of the original trouble, and had healed as a result of the incision into the kidney.

The Early Diagnosis of Pulmonary Tuberculosis.—Ernst Levy and Hugo Bruns insist upon taking the entire amount of sputum for the twenty-four hours for examination, as the bacilli are not always present, and repeated examinations at not too long intervals must be made. In case of a negative result from sputum examination, resort should be had to animal inoculations. The authors also use the original tuberculin for diagnostic purposes, and believe that with care in its employment no harm can come from it.

Pathology and Treatment of Lamellar Cataract.—Bähr reports on 153 cases of lamellar cataract operated upon in Hirschberg's clinic. Of these 92 were in male, and 61 in female subjects. In 7 the cataract was single, in all the others double. In 136 cases there were symptoms of rickets. The treatment that gives the best results in children is discission.

Severe Nervous Symptoms Caused by the Presence of Intestinal Worms.—Max Heim reports two cases of severe nervous symptoms and nutritional disturbances in infants under one year of age which were caused by the presence of lumbricoid worms. These symptoms disappeared at once upon the expulsion of the parasites from the intestine.

Orthopedic Treatment of Malpositions of the Uterus.—By G. Zepler; a continued article.

A New Instrument for Vibration Massage.—A. Eulenberg describes a new instrument of his device.

Münchener med. Wochenschrift, Feb. 20 and 27, 1900.

Contribution to the Knowledge of Alexins, as regards their Specifically Bactericidal and Hæmolytic Influences.—H. Buchner says there is no doubt that Leber has positively proved by his experiments the important fact of histolysis and proteolysis through the agency of the leucocytes, this being in perfect agreement with their general function as absorption cells. He says further that the idea of the existence of specifically bactericidal material must, as far as he is concerned, be definitely laid aside. He believes that bactericidal properties and specificity belong to different kinds of substances, viz., alexins and antitoxins, respectively. The bactericidal and hæmolytic properties of alexins possess nothing of the character of specificity. Everything of specific nature belongs to the antitoxins.

Clinical Contribution to the Symptomatology of Pancreatitis Acuta.—Hans Doerfler reports a case of acute suppurative pancreatitis and necrosis of the pancreatic tissue. There were severe lumbar pains from the beginning to near the end of the disease. Since section offered no other explanation, there can be no doubt that these pains were caused either by the pressure of the pancreas, enlarged by inflammation, on the solar plexus and the semilunar ganglion, or by an extension of this inflammation to these structures. Osler and Hughes have in acute pancreatitis found round-celled infiltration in the ganglia and inflammatory changes in the nerve cells. Also a striking feature was the great distention of the ascending and transverse colon and their sharp limitation from the entire descending colon.

Hydrorrhœa Ovarialis Intermittens: A Contribution to the Knowledge of Tubo-Ovarian Cysts.—Max Nassauer, in reviewing this subject, says that in all probability there occurs in all cases an antecedent gonorrhœa causing the tubo-ovarian cyst, which constitutes the origin of the hydrorrhœa. First, there is a gonorrhœal inflammation of the tube, which extends to the ovary and the pelvic peritoneum on the same side. Here the cyst is formed, and when it bursts the adherent tube drops into it, the fimbriated extremity of the tube adhering to the edges of the rent in the cyst wall, and in this way the cystic fluid gains access to the tube. The evacuation of the fluid takes place periodically.

On the Occurrence of "Riding-Pain" in the Patella.—J. A. Rosenberger speaks of three cases of this kind. The prognosis is absolutely good; for when the cause, *i.e.*, pressure, is eliminated, the pain is relieved. Severe pain disappears in the first days. Therapeutically, relief from pressure and absolute rest are indicated. Recovery will always follow. Rubbing and the bath are valuable remedies. Massage in the early treatment cannot be considered, as it increases pain. On account of the absolutely negative findings in this affection, the physician might think of simulation or exaggeration.

The Influence of Spinal Puncture and the Condition of the Spinal Fluid in Chronic Hydrocephalus.—Julius A. Grober reports two cases, and says that their clinical significance lies without doubt in the fact that it is possible to cure chronic hydrocephalus. Whether this is permanent or only for a time, further observation must show. That frequent repetition of spinal puncture has played an important, if not the chief, rôle in this treatment, is apparent from the observation of other hydrocephalic children.

A Method of Treatment of Lung Tuberculosis with Subcutaneous Injections of Oil of Camphor.—B. Alexander states that from the beginning he daily injected 0.1 gm. camphor. For patients with fever he daily injected 0.01–0.02 gm., or in cases of great weakness 0.03 gm., of camphor for a week or a month without interruption. Patients free from fever were treated likewise, or had injected daily 0.1 gm. camphor for four days; then after intervals of at least eight days these are repeated.

Clinical Contribution to Intestinal Lipoma.—Florian Hahn states that lipomata of the digestive tract are rare tumors. The interesting points in this case are that the lipoma was multiple in the submucosa, and that there was the combination of external and internal lipoma; also that there was sclerosis of the intestinal wall in the position of a degenerated lipoma. It is the first case of invagination from lipoma in which recovery took place through resection.

A Case of Self-Injury with Hysterical Basis.—J. Eversmann relates the case of a woman on whose body—hands and arms particularly—water blisters appeared, no cause being apparent. It was finally discovered that the patient herself applied cantharides plasters when free from observation.

A Case of Friedrich's Ataxia.—C. Wickel gives the history of this case, and in speaking of the etiology notes phthisis in the father. The child was always sickly. This weakness may have caused a tendency to affections of the central nervous system. Lues was not proved in the father.

On the After-Treatment of Severe Abdominal Operations.—Steinthal believes in the efficacy of regularly repeated intravenous infusions of physiological salt solution, in connection with subcutaneous oil injections and nutrient enemata.

Angina with Endocarditis.—Roeger speaks of the frequency of this combination. The treatment of endocarditis consists in the application of an ice-bottle to the precordia, absolute rest in bed, and avoidance of stimulating drinks.

The Relation between Scrofula and Trachoma.—S. Bäck states that there exists a certain causal connection between trachoma and scrofula of the eye. Both perhaps may be traced to the same etiological factor.

Treatment of Suppuration of the Eyes in the New-Born.—A. Lamhofer washes out the eyes every hour or two with lukewarm water. If medication is necessary, he uses weak boric or alum solution.

A Rare Case of Paralysis of the Radialis Cured by Freely Exposing and Stretching the Nerve.—Hans Bräuninger reports this successfully treated case. The patient was a youth, sixteen years old.

The Therapy of Lupus and Skin Diseases by Means of Roentgen Rays.—By R. Hahn and Albers Schönberg.

Berliner klinische Wochenschrift, Feb. 26, 1900.

Clinical Significance and Experimental Production of Granular Degeneration of the Red Blood Cells.—E. Grawitz discusses the occurrence of this condition as seen in various diseased states. He does not regard it as an absolute or specific process occurring in the cells, but as a simple degeneration which can arise from many causes, and he cautions against drawing hasty conclusions with reference to its causative relation to any definite pathological condition. He has found that it may be induced in white mice by subjecting them to the prolonged influence of a moderately high temperature.

Nature's Methods of Protecting the Organism against Infection.—In this issue, P. Baumgarten concludes a lengthy polemic (running through two previous numbers) against the views of H. Buechner. He takes a very conservative view as to the bactericidal properties of normal serum, claiming that some of the theories which have been set forth in this regard are not proven by clinical experience, and that a too hasty transference of conclusions from laboratory experience to the domain of actual treatment of disease has been made.

Researches on the Bacterial Contents of Brushes, and the Possibility of Sterilizing them.—A. Winternitz finds that it is possible to sterilize brushes (no matter how long they may have been infected) by boiling them for ten minutes in a one-per-cent. soda solution, and that they may be kept sterile by preservation in a solution of sublimate, 1 : 1,000.

Syphilis of the Lingual Tonsil.—J. Heller makes a statistical study of the frequency of this localization of the specific poison. He discusses the various forms of lesion seen in this situation, paying special attention to the so-called flat atrophy of the tongue.

Vratch, February 12, 1900.

Etiology and Treatment of Angina Pectoris.—Th. K. Geisler discusses that form of angina which occurs in consequence of vasomotor disturbances at the menopause, and formulates the following conclusions: 1. Attacks of angina pectoris observed for the first time at the menopause may be dependent upon the changes occurring at this period, or they may accidentally begin at this time from other and unassociated causes. 2. In the former case the attacks may be purely neurasthenic or hysterical, or they may be of vasomotor origin (spasm of the coronary arteries), giving the picture of severe organic angina pectoris. These two forms may, of course, be combined. 3. In the presence of angina immediately dependent upon the approaching climacteric our first resort should be to specific treatment with ovarian extract.

The High Operation for Stone.—V. I. Lisïanski reports fifty cases of vesical calculus removed by the high operation. There were two deaths from extraneous causes, but none attributable to the operation itself. The stone was solitary in every case but one; in this one case there were two stones. The author advises immediate suture of the bladder in moderately young and well-nourished patients and when the urine is healthy.

Rhinoplasty by Israel's Method.—M. M. Kuznetsoff reports two cases of rhinoplasty for saddle-nose performed after the method of J. Israel. This consists of two steps: (1) The transplantation under the skin of the nose of a piece of bone chiselled from the tibia to supply the bony ridge; (2) A modified Italian rhinoplasty.

Endothelial Neoplasms of the Gastro-Enteric Tract.—By L. V. Soboleff. A continued article.

La Riforma Medica, Feb. 15 to March 1, 1900.

The Cure of Cutaneous Epitheliomata by the Cerny-Trunecek Method.—Cesare Casarini holds that in applying the arsenic cure we should always have recourse to microscopical examinations so as to ascertain whether the prevalence of one histological element over another at all affects the cure. No great importance can be attached to a cure obtained in superficial epitheliomata, since other remedies have also given good results. Still, arsenious acid does hasten cicatrization. The application of the remedy is easy, and, although painful, is usually well supported by the patient.

Hydrocele.—Nicolino Ferrici says that the operation preferred in Roth's clinic is that of Hüter, opening at the inferior end of the tumor, emptying, making a counter-opening above, a long closed forceps being introduced into the sac serving as guide, and drainage. Irrigations are made with a hot boric-acid solution. The aseptic irritation produced by the drainage is usually sufficient to provoke adhesion of the serous surfaces. In rare cases when adhesion is tardy, recourse may be had to one or two irrigations with an iodine solution. The majority of cases result in cure in twenty days.

Uses of the Stomach-Tube in Gastropathy, and Indications for Gastro-Enterostomy.—E. Tricomi says that gastro-enterostomy has already had great triumphs, and that physicians are convinced that in cancer of the stomach benign stenosis, simple gastric ulcer, gastro-succorrhœa, obstinate idiopathic gastrectasy, and some cases of special functional disturbance are best treated by this operation, either alone or combined with resection of the stomach. In the case of cancer there are some cures which have lasted five, seven, and ten years.

The Influence of the Nervous System on the Cure of Fractures.—E. Arcoleo concludes from clinical observation and laboratory experiments that: (1) Excision of the sympathetic in dogs has no influence upon the process of recovery in fractures, which goes on normally; (2) the nervous system has no influence on the formation of the callus in fractures; (3) clinical observations confirm laboratory experimentation.

The Action of Adonis Vernalis in Epilepsy.—G. Gianni believes that this drug may have some influence in attenuating the attacks, but that it may cause them to occur more frequently. It has no advantage over bromide.

A New and Economical Thermostat.—C. Tauzig describes a simple thermostat, easy of construction. and of practical value.

French Journals.

Intoxications following the Ingestion of Molluscs.—Dr. Mosny concludes his article with the propositions: (1) The bacteriological analysis of the organs of molluscs and of the water retained in their shells has revealed the presence of bacteria pathogenic for man, in particular those of typhoid fever, the coli bacillus, and vibrios similar to those of cholera. (2) Experiments have shown that certain pathogenic microbes, and in particular the Eberth bacillus, the coli bacillus, and the vibrio of cholera, artificially placed in contact with oysters, could remain living and virulent in the organism of these molluscs and in the water retained between the valves of their shells, for a longer period than usually elapses between their being taken out of the water and sold for consumption. —*Journal des Praticiens*, February 24, 1900.

Contusive Pneumonia.—A. Sauques says that trauma, and especially thoracic traumatism, may provoke and localize lobar pneumonia by simple contusion. Gamaleïa was able to produce lobar pneumonia in an animal only by injuring the lung, either in inoculating the pneumococcus through the thoracic wall or introducing it by way of the trachea, after having first injected tartar emetic. Experiment has shown that traumatism prepared the way for infection in determining a trouble of the vasomotor system of reflex origin. The rôle and mechanism of traumatism in the development of contusive pneumonia are solidly established.—*La Presse Médicale*, March 3, 1900.

The Plague in Ancient and Modern Times, and its Future in Europe.—Ph. Hauser completes his serial article with a consideration of the future of the plague.—*La Médecine Moderne*, March 3, 1900.

Bulletin de l'Académie de Méd., Feb. 20 and 27, 1900.

Attenuated Forms of Grippe and their Treatment.—H. Huchard classifies these forms as the apyretic, characterized by neuralgias, by nervous asthenia, by general depression, by gastro-intestinal troubles; and the febrile, shown by fever alone. These types often lead on to more severe forms. The author considers quinine sulphate the best possible medicament for this affection, and from the onset prescribes from 1 to 1.5 gm. the first day, and perhaps for several days in succession. He recommends a simple diet, and the ingestion of much milk.

Disinfection in Measles.—E. Vallin says that as in Paris deaths from measles are more frequent than from any other infectious disease except tuberculosis—eight hundred and fifty deaths in 1899; two hundred and fifty from typhoid and from diphtheria—disinfection should be more rigorously practised.

Rhinoplasty.—Paul Berger built up an entire nose by enclosing a metallic bridge between two flaps that were made to unite with each other by first intention. This obviated all possibility of infection, and the result was satisfactory.

Psoriasis.—M. Petrini reports a case cured by the administration of thyroid gland in capsules.

Journal of Nervous and Mental Disease, March, 1900.

The Relation between Trigeminal Neuralgias and Migraine.—James J. Putnam claims that recurrent ophthalmic neuralgia stands out vividly from among the other neuralgias of the trigeminal nerve, and that some of the characteristics that it presents strikingly recall migraine, so that the study of either disease throws light on our knowledge of the other. The difference between "neuralgias" and migraine he believes to be one of degree rather than of kind, due partly to the fact that the centres involved in the case of migraine are of such high functional significance and united in such wide and close association with other cerebral areas.

Lesions of the Optic Chiasm.—William M. Leszynsky divides these lesions into four classes: (1) Associated with intracranial growths and their concomitant symptomatology; (2) from enlargement of the prehypophysis cerebri, as occurring in acromegaly; (3) in syphilitic basal meningitis; (4) from a circumscribed pathological process, which gradually produces complete atrophy of both optic nerves, without any cerebral symptoms whatever.

Epileptic Ambulatory Automatism.—D. J. McCarthy reports a case of that condition, in which an individual consciously or unconsciously performs more or less complex ambulatory acts over which he has no control.

The Edinburgh Medical Journal, March, 1900.

On the Method of Zadig in the Advancement of Medicine.—George W. Balfour, in a review of what has been done by medical science by means of a careful search for that efficient cause which must always precede every effect, speaks of microbes which, although always with us and around us, do us no harm, because when in good health our natural antitoxin is sufficient to neutralize the toxin with which they endeavor to flood our tissues. This is the basis of the Nordrach treatment of phthisis, by forced feeding and free exposure to sunlight and fresh air to increase the natural antitoxin, and thus overcome the toxin of the tubercle bacillus.

Food versus Physic.—John Haddon says that all the nitrogen we require is just as much as will supply the small amount of tissue waste that takes place, and that when we eat much food rich in nitrogen, such as meat, we are putting into our bodies a substance which acts as a foreign body, and must be got rid of by the digestive and excretory organs in the form of urea. It is small wonder therefore, he thinks, that sooner or later we suffer from symptoms due to the ingestion of nitrogen. He believes in making all "gouty" sufferers strict vegetarians.

The Place of Protargol in Eye-Work.—Sydney Stephenson believes that although protargol is not an absolutely ideal agent in treating inflammatory affections of the eye, it is in some respects an important advance upon silver nitrate.

Molluscum Fibrosum.—G. L. Kerr Pringle reports a case which shows both the small soft tumors and the large pedunculated masses. The pigmentation of the body is also disturbed.

Some Observations on Vascular Resistance.—Harry Campbell considers the objects served by arteriolar resistance, and those served by the reduction of the systemic venous resistance to the minimum.

Ulcer of the Cornea.—A. Maitland Ramsay gives a detailed description of this affection, with its etiology, complications, sequelæ, prognosis, and treatment.

The Differential Diagnosis of Gout, Rheumatism, and Rheumatoid Arthritis.—Arthur P. Luff gives rules for the recognition of these three conditions.

Dublin Medical Journal, March, 1900.

The Position of the Murphy's Button in Modern Surgery.—J. S. McArdle concludes in this issue a study of the development of this device, and gives clinical histories of eight cases in which he has used it. He enumerates, as objections which have been urged against it, contraction of the intestine at the site of operation, sloughing from pressure, septic peritonitis, retention of the button, kinking of the bowel, faulty position of the button, difficulty of rectification when once it has been inserted, difficulty of having the proper size on hand, and the expense of the appliance. He does not regard any of these objections as valid. He claims that its use has reduced the mortality of operation from sixty to thirty per cent.

The Rôle of the Municipality in Public Hygiene.—By Sir C. A. Cameron. A presidential address to the Leinster branch of the British Medical Association, February 6, 1900.

Clinical Reports of the Rotunda Hospitals for One Year, November 1, 1898, to October 31, 1899.—By R. D. Purefoy, R. P. Lyle, and H. C. Lloyd.

Zeitschr. f. Diätet. und Physik. Therapie, Feb., 1900.

Treatment of Chronic Ulcer of the Stomach.—August Richter says that in treating this condition the amount of gastric mucus is the first consideration. Only in cases in which he thinks the edges of the ulcer clean and the wall of the stomach smooth and free from mucus, when a certain hyperæsthesia of the sensory nerves of the stomach exists, and the amount of hydrochloric acid is not much increased or normal, is the solution of silver nitrate useful.

The Significance of the Hot-Air Douche in Aerotherapy.—A. Frey, after describing the apparatus, concludes that with it we may produce hyperæmia or anæmia over any given vascular area and maintain it so that the energy of the cells may be increased or diminished. The more extreme the temperatures the more intense are the local results.

Value of Occupation in the Treatment of Disease.—F. Buttersack states that there are two points of importance in reference to the course of disease: (1) The worry which fathers and mothers have about the family; (2) the filling in of time during convalescence.

Treatment of Diabetes at the Menopause.—E. Heinrich Kisch states that the physician must combine a psychical and physical diet in these cases. The patient's time should be fully occupied and the thoughts drawn from unpleasant things.

The Chemical Composition and Effect of the Inorganic Salt Solution according to the Theories of Modern Chemistry.—R. Brasch compares and analyzes Kissingen, Rakoczy, and Carlsbad Sprudel. Several tables accompany the article.

The Blood-Purifying Diet of Galen.—Basler contributes an article comparing the diet in the days of Galen with that of modern times.

Deutsche Aerzte-Zeitung, March 1, 1900.

Prophylaxis of Pulmonary Tuberculosis.—G. Krönig takes the ground that the greater are the natural defences against invasion the greater is the guarantee of escape from tuberculosis. A well-built man with healthy organs has little to fear. The early evidences of tuberculosis of the lung apex are to be best secured by topographical percussion of the apex region; a modification of Biedert's method of finding the bacilli as given by the writer; and a careful investigation of the general condition of the patient.

Clinical Experience with Oxy-Camphor (Oxaphor).—Franz Meyer discusses this drug, which, like heroin, diminishes excitability of the respiratory centre. It was discovered by Manasse, of Munich, in attempting to find derivatives of camphor which would be more soluble than camphor itself. In dyspnœa it is capable of doing good work, and in daily dose of 2 to 4 gm. seems to be harmless. It has the disadvantage of being still quite dear.

On the Origin of Inguinal Hernia.—By Graser. A continued article.

Giornale Medico del Regio Esercito, January 31, 1900.

Angiotripsy.—Attilio Bruni describes the process of arresting hemorrhage by means of Cavazzani's angiotribe. The advantages of the method are its rapidity, and the absence of secondary hemorrhage. For small vessels it is in itself sufficient, and in large ones it may be used in combination with a very slender ligature. Thumin by histological examination has found that hæmostasis is produced, not only by retraction and constriction of the arteries, but by immediate occlusion of the vessel from union of the endothelial coat.

Biliary Lithiasis; Perforation of the Gall Bladder; Acute Peritonitis.—Pasquale Tecce reports a case which terminated fatally, and in which examination of the calculi showed that the two largest of the five examined contained a foreign body. These vegetable fragments must have come from the intestines; a fact which upholds the latest clinical theories that calculus is due to purely local conditions of the biliary passages, instead of to chemical changes.

Annali di Medicina Navale, January, 1900.

The Technique of Suprapubic Cystotomy.—Francesco Rossi gives in detail the procedures to be adopted in this operation, to avoid wounding the peritoneum, and so to treat the wound as to prevent infiltration of urine or to render it innocuous. These details, he says, being a résumé of the most recent procedures of various authorities, have not as yet been described in any work on operative surgery.

Rapidly Fatal Hæmatemesis from Hepatic Cirrhosis.—F. Antonelli reports the case of a sailor who, feeling gastric oppression, endeavored to empty his stomach by vomiting. Fatal hæmatemesis followed. The liver was found to be cirrhotic.

Disinfection of the Hands.—Gaetano Tacchetti describes the method in use in Bassini's clinic in Padua, who has the greatest success in obtaining primary union after operation.

Case of Psychical Epilepsy.—R. Cesàro reports a case in which sudden attacks of hallucination and other psychic-sensorial disturbances, evidently epileptic in their nature, replaced the typical motor attack.

Paroxysmal Bradycardia.—A. Luzzati describes a case due to nicotine poisoning.

Corresp. f. Schweizer Aerzte, Feb. 15 and March 1, 1900.

Two Cases of Tetanus Treated with Antitoxin.—Kocher relates two instances treated at the institute for the investigation of infectious diseases in Berne. In the case of a man, aged thirty-two years, injured upon the head twenty-seven days before, recovery took place after intracerebral injection of 10 c.c. and an intravenous injection of 50 c.c. of serum in the median vein. In a child, aged five years, injured a week before upon the eyelid, the symptoms and course were so acute that there was little hope. An intracerebral injection was made, but the child died the same day.

Intestinal Bacteria and Intestinal Bacterial Poison in the Brain.—Johannes Seitz discusses auto-infection or auto-intoxication, giving details of cases; and touches upon the use of opium in peritonitis. Convulsions in children and unexpected death are explained by invasion of the brain by intestinal bacteria, especially the coli bacterium, without giving rise to meningeal inflammation. In seven out of fifteen cases the bacteria of the intestinal contents were thought to be the cause of the head symptoms.

Ozæna.—F. Siebenmann discusses rhinitis atrophica simplex and fœtida with its constantly accompanying pharyngitis sicca. He thinks that the family physician, who sees the patient frequently and can control him, is better constituted to obtain good results than the specialist to whom occasional visits are paid.

Annales de Gynécologie et d'Obstetrique, Feb., 1900.

Indications for Operation in Cases of Fibroma Complicated by Pregnancy.—H. Delagénière believes that when severe pain is caused by compression of the pelvic organs, or by a tumor incarcerated in the pelvis; when ureters, bladder, or rectum are compressed by a tumor situated in the inferior portion of the uterus; when hemorrhage or placental apoplexy threaten the life of the fœtus, operation should be performed. Abortion or premature labor should never be induced, the rate of mortality being very much greater than in the case of radical operations.

Phlegmonous Dissecting Perivaginitis.—Von Lingen reports a case in a woman, thirty-nine years of age, married, nullipara. The vagina, cul-de-sac, and cervix uteri were gangrenous, and were thrown off. Absolutely no cause could be found for the condition.

Right Hydrosalpingitis with Twisted Pedicle.—M. Hartmann reports a case complicated by adhesive peritonitis and appendicitis. The right appendages and the appendix were removed, and the patient made a good recovery.

Parovarian Cyst.—E. Jeanbrau and J. Moitessier report a case in which the cyst contained twenty-three litres of albuminous fluid.

Archives Générales de Médecine, March, 1900.

Regeneration and Cicatrization as Related to Embryonal Development.—Etienne Rabaud says that as a result of studies in comparative embryology, it is evident that regeneration follows the paths of embryonal development. Homomorphism is the rule, that is to say, the organ is usually regenerated in its usual form and dimensions, but there are exceptions. Regeneration follows the laws of ontogenetic or phylogenetic development; that is to say, the derivation of the epiblast, while still in dependence upon its surroundings.

Purpura and Visceral Affections.—C. Oddo and Olmer, concluding an article from the previous number, state that while purpura may in many cases have no apparent connection with visceral lesions, yet it often is related to anterior affections of the bronchi, lungs, tonsils, and intestines, which serve as the door of entrance to the infective agent, causing purpura. Sometimes the visceral affections cause purpura by altered nutrition and auto-intoxication. Visceral affections existing contemporaneously with purpura are due to the causative toxic infection.

Botryomycosis.—In concluding an article begun in the previous number, Antonin Poncet and Louis Dor give the result of investigations into the nature of these growths which occur in horses after castration, and are also found on the human hand and fingers. They have found it to be due to a special micro-organism called the botryococcus, which has many points of resemblance to the staphylococcus pyogenes, but is not identical with it. There is a human botryococcus as well as an equine.

Organic Hemichorea.—M. Touche says that this affection may be produced by a lesion of the (1) corona radiata; (2) caudate nucleus; (3) anterior portion of the lenticular nucleus; (4) optic thalamus, usually of its external nucleus; (5) internal capsule; (6) region below the optic thalamus, involving the red nucleus; (7) superior surface of the cerebellum.

Cerebral Tumor of Psychoparalytic Form.—Brault and Loeper report three cases. Tumors of the motor region may be manifested only by progressive paralyses and psychical affections. This association of symptoms causes a suspicion of cerebral tumor; an ophthalmoscopic examination is necessary to decide the matter.

Malarial Cachexia.—E. Lefas reports a case in which there was general amyloid degeneration, but total absence of pigmentation in the blood and viscera.

Finska Läkaresällskapets Handlingar, February, 1900.

Hæmatometra in a Rudimentary Horn of the Uterus.—O. A. Boije reports the case of a woman, twenty-seven years old, the mother of three children, who had always enjoyed good health except at the menstrual periods, when she suffered greatly. An oval tumor the size of a hen's egg was felt to the right of the womb and was diagnosed as a pedunculated fibroid. At the operation, however, its true nature was discovered. There was no communication with the cavity of the uterus.

The Work of the Finland Medical Society for 1899.—R. Sievers, the retiring president, states that seventy-two communications by twenty-four individuals were made to the society in the course of the year, and forty-four original articles by thirty-three authors were published in the journal of the society. The seventeenth general congress of Finnish physicians was held on September 21st–23d.

The Electrolytic Properties of the Blood.—Max Oker-Blom reports a number of investigations made to determine the electric conduction of defibrinated blood and of blood serum, and describes a method based upon the differences of conduction, whereby he determines whether a given salt is taken up by the erythrocytes or remains dissolved in the serum.

Traumatic Spondylitis with Subsequent Kyphosis.—H. von Bonsdorff reports two cases of this nature, the first in a man aged twenty-five years, and the second in a lad aged nineteen years.

Meditsinskoe Obozrenie, February, 1900.

Acute Yellow Atrophy of the Liver.—E. M. Schwalbe reports a case of this rare affection occurring in a girl, aged sixteen years. She had been ill a week when she first came under observation, and died a week later. He believes the disease to be the result of some poisonous product, elaborated in the stomach or intestine, and carried to the liver by the blood of the portal vein; but whether this poison is a product of bacterial metabolism or of some abnormal fermentation in the digestive tract he does not venture to decide.

Hereditary Syringomyelia.—S. S. Nalbandoff reports the case of a man, thirty-three years of age, who presented symptoms of syringomyelia. His father had died of laryngeal tuberculosis, and his mother, he said, was a sufferer from "rheumatism of the fingers." She was fifty-five years old, and examination showed that she too had the same disease. Authors usually deny that heredity is an etiological factor in this affection, although Ferrannini and Veshoogen and Vandervelde have written upon syringomyelia as a familial disease.

Adenoids.—I. N. Teterevïatnikoff discusses the frequency of adenoid disease, its relation to aural affections, and its influence in the causation of aprosexia in school children. He reports three cases of unusually brilliant results, following the removal of adenoid tissue from the pharynx.

Primary Sarcoma of the Gall Bladder.—P. M. Nevïadomski reports a case of this description, occurring in a woman fifty-five years old, in which there was found at autopsy a diffuse sarcomatous infiltration of the visceral peritoneum.

Anchoring a Wandering Kidney.—P. A. Baratynski reports a case of movable kidney in a woman, thirty-three years of age, in which he succeeded in removing the distressing nervous symptoms by suturing the kidney in place.

Hereditary Syringomelia.—P. A. Preobrazhenski reports three cases of syringomyelia, the first in a man sixty-five years old, the second and third in two of his daughters, aged thirty-two and eighteen years respectively.

Correspondence.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

The Boer Arrangements for their Sick are becoming better known, and, as I have already been able to say, have been underrated. But the Boers have availed themselves considerably, though reluctantly, of foreign assistance. Six foreign sanitary detachments or ambulances have been admitted to the Boer lines. Two of these were Dutch, one coming from Holland and the other from Java; while the other four came respectively from Belgium, France, Germany, and Russia. A second Russian ambulance has been fitted out, but it has not yet reached its destination. Professor Korteweg, surgeon at the University Clinic in Amsterdam, who served for two months with the Boers—*i.e.*, from the middle of November to the middle of January—reports that the attitude of the Boers toward the foreign nations desirous of helping them is not conciliatory. The foreign medical men and nurses had great difficulty in finding out where their services would be most required, as for strategical reasons it was never indicated where fighting was likely to take place. This want of confidence of the Boers in all European nations was well shown in the treatment that Sir James Sivewright's ambulance received. Sir

James Sivewright, K.C.M.G., who was for many years general manager of South African telegraphs, and who was knighted for his work as commissioner of crown lands in Cape Colony, has strong Boer sympathies. He organized and despatched from Scotland at his own expense a South African medical corps for ambulance service with the Boers. When the ambulance, which was manned partly by Boers receiving their medical education in Scotch universities, and partly by British, arrived at Cape Town, the assistance offered was refused by the Transvaal government. The ambulance, however, proceeded to Delagoa Bay, where certain overtures were made to induce its members to individually volunteer to assist the Transvaal. The British members of the corps regarded these overtures with suspicion and did not volunteer, for Sir James Sivewright's intentions were humanitarian and not dictated by any political motives; whereas, as Mr. Allan Johnson, one of the three British members of the corps, has publicly said, "While the Transvaal government were quite willing to receive any number of Afrikanders into their service, they would not look at an ambulance corps which included Britishers, especially if these showed that they meant to stick tenaciously to their pledge to work for the wounded of every sort and race." Sir James Sivewright's action has been generally held to be unpatriotic and unnecessary, so that the cold and limited reception awarded to his ambulance by the Republican States has been a source of amusement in Cape Town.

Touch and Go at Ladysmith.—It is now known that Ladysmith could not have held out much longer, but that sickness and starvation would have compelled the garrison, which included five hundred women and children, and eight hundred persons sick with typhoid fever, to capitulate. The day Ladysmith was relieved the rations actually issued were (per head) a quarter of a pound of biscuit, three ounces of meal, one pound of meat, one-sixth of an ounce of tea, one ounce of sugar, and pinches of salt and pepper. Blancmanges were being made of violet powder, potatoes were 19*s.* the dozen, jam and marmalade 31*s.* the pot, tomatoes 18*s.* the dozen, and tobacco £12 the pound. Only about four days' full rations remained when Buller's fourth and furious attack dislodged the Boers and relieved the place.

The Cost of the Medical Establishment of the British Army.—The effects of the war, as might be expected, can be traced in the estimates for the medical establishment of the army which were disclosed in the fiscal debates in the British House of Commons at the beginning of March. The total vote for 1899–1900 was £305,800, whereas for 1900–1901 it is £555,000. Under the head of pay to the officers there is an increase of £120,000, which is to some extent accounted for by the fact that the civilian surgeons serving in a consultant capacity with the staffs are being paid at the rate of £5,000 per annum. Provision is being made in the estimates for a large increase of officers in the Royal Army Medical Corps. That the addition is needed has been abundantly proved by recent events, but the War Office will not get more men unless they make up their minds to treat the men they already have in a more conciliatory manner than so far has been the custom. They say that the Royal Army Medical Corps have reason to believe that the present commander-in-chief, Viscount Wolseley, regards their branch of the service with disfavor. But Lord Wolseley's disfavor will not mean so much in the future as it has in the past.

The Meat on Board the Transports.—There have been many rumors that on board some of the transports the troops were badly fed. All these stories have now been rigorously inquired into, with the result that nearly every one has been discredited. But in one case, viz., on board the *Kildonen Castle*, eighteen hundred and forty-two pounds of salt beef was found to be dated "1893," and was consequently returned to the contractors. It is to be hoped that the names of the firms who in this or any other way have attempted to cheat their country will be disclosed. The punishment will be sufficient, without other penalties, of having their names published. Yet it would be advisable to punish them severely in addition.

One Way to Fill the British Hospitals.—The transports conveying troops from Great Britain to Cape Town have recently dropped a great number of men in the Cape Town hospitals. The medical officers of those establishments complain that more care might be exercised in the medical examination at home of men destined for duty at the front; cases of hernia, for example, ought to be detected, when they exist, prior to embarkation. Such patients take up badly wanted accommodation in the various hospitals, and in some instances never get farther than the wards until placed upon a homeward-bound trooper—a decidedly expensive matter for the British government. The medical men serving with the British army consider that the reserves and militia who have lately arrived in South Africa are somewhat disappointing from a physical point of view, which may mean only that the inspection of their physique in England has been carried out in a slovenly or ignorant manner, or may mean that for the present, as far as efficient regular troops are concerned, the supply is running short. The amount of breakdowns in the health of the reservists has come as a surprise to the authorities.

To the Front Again.—If the good weather persists and if there are occasional lulls in the fighting, the hospital accommodation, all of which I have now detailed to you, will suffice, in spite of the heavy demands made upon it. For the slightly wounded get back to the front quickly, while the convalescent are regularly transported to England if they are unfit to serve again. On March 7th there were discharged at Durban twenty-two men from the *Spartan* hospital ship, twenty-eight from the *Maine*, eleven from the *Lismore Castle*, and thirty-eight from the *Nubia*, all being reported as fit for active service again. While the recently wounded return to the front at this rate, there will always be a good deal of space for other unlucky soldiers. But on March 10th Lord Roberts had rolled up ahead of him a large Boer army, of presumably ten thousand men, so that a sanguinary engagement may at any moment call upon the Royal Army Medical Corps for their best services.

OUR LONDON LETTER.

(From our Special Correspondent.)

PARLIAMENTARY—MIDWIVES, ETC.—DEBATE AT THE PATHOLOGICAL SOCIETY ON PROTEIDS IN THE URINE—THE MEDICAL SOCIETY'S ADJOURNED DISCUSSION ON APPENDICITIS.

London, March 2, 1900.

As I predicted, the midwives' bill came on too late on Wednesday. Its fate is probably sealed for this year, as it can be taken only at the close of public business, but an eye must be kept on the chance of its slipping through on some unexpected vacancy at a late hour. Other medical matters in Parliament have been connected with the army and navy services and events in South Africa; the plague and famine in India; the government housing bill, and the bill for the census to be taken next year.

Another set debate has been begun at the Pathological Society. The subject this time is "The Forms and Significance of the Proteids Met with in the

Urine." Professor Halliburton opened the discussion with remarks on the advantage of pathologists and clinical observers co-operating in such debates, passing on to say that our knowledge of these proteids is still very imperfect, though each year marks some progress. These proteids he said were of great molecular weight, and their large size explained why they do not pierce the normal renal epithelium except in minutest traces. That which does is contained in the mucicula, though he admitted with Mörner that a trace of serum albumin is found in normal urine. Serum albumin was also most abundant in physiological albuminuria; but in Bright's disease it is usually mixed with serum globulin. Generally the globulin was the less abundant and its presence less serious. There was some evidence that the molecules of globulin were the larger, which would account for the greater abundance of the albumin. Only after damage to the epithelial cells could the globulin pass through them. The fibrinogen molecule was still larger, and hence its rarity in the urine. The same reason accounted for caseinogen never having been found in cases were lactose discoverable. Having passed in review some other rare proteids, Dr. Halliburton turned to those with small molecules. He distinguished between peptonuria and albumosuria. He would restrict the former term to those conditions, usually of a suppurating nature, in which bacterial digestion led to the formation of proteolytic products which were mainly cast out by the kidneys. The substance most frequently found was not true peptone in Kühne's sense, but deutero-proteose. The term albumosuria was usually restricted to those rare cases in which hetero-albumose was found, due to osteomalacia or other bone disease.

Dr. Bradshaw, of Liverpool, then dealt with myelopathic albumosuria, of which only eleven cases had been recorded. He had met with one case in a man aged seventy years which lasted about a year. There was extensive disease of the bones, but the chief symptom was milky urine due to a proteid which was frequently precipitated spontaneously. The most characteristic reactions were a precipitate below 60° C. (140° F.), also in the cold by nitric and hydrochloric acids. All precipitates were more or less soluble on boiling; that produced by heat was dissolved without apparent change by caustic-soda solution 1:1,000. The proteid was clearly an albumose, but of a peculiar kind not found in other conditions. Its appearance in the urine is the earliest indication of an affection of the bones of the trunk, which has hitherto always been fatal.

Dr. Robert Hutchison then described a peculiar proteid found in the urine of a man who afterward died from multiple myeloid sarcoma. It differed from the body described by Bence Jones in being an albumin, not an albumose. It differed too from all other albumins in having a low coagulation point (58° C.), in being readily denaturalized and only slowly precipitated by acetic acid and ferrocyanide of potassium. The urine presented no visible deposit but was clear, of low specific gravity, and slightly alkaline.

Dr. Pavy could not admit that albumin in any form occurred in normal urine. We might perhaps have functional albuminuria that is not due to histological change in the kidney, but then it was pathological, not physiological. The molecule of sugar was very small, so if present in the blood it would pass through the kidneys. But although normal urine contained no albumin it might contain a small amount of proteid as a nucleo-albumin or mucin. This was sometimes the origin of errors. The urine of the athlete who walked one hundred miles in twenty-four hours Dr. Pavy found to be loaded with albumin and casts at the close of the exploit. The altered pressure in the renal vessels would account for cases of cyclic albuminuria occurring in the morning and being absent at night. The proportion between albumin and globulin had not been shown to be of importance, clinically or pathologically, nor was the total amount of proteid significant. The gravity of the case was to be measured by the presence of casts and the amount of urine passed.

The discussion was then adjourned to the first meeting in April.

The adjourned discussion on appendicitis at the Medical Society came off on Monday. Mr. Sheild said the absence of induration over the cæcum need not preclude operation. Rapid pulse was a very important sign. He was against a resort to opium unless in very small dose, and he urged the importance of getting the bowels to act.

Dr. Cayley would carefully distinguish mild cases from the actually or the potentially severe ones. But he acknowledged that when severe symptoms appeared early in the case it was impossible to know whether they would subside or continue their grave course. Rapidity of pulse was significant, but should be considered in connection with other symptoms. He thought opium beneficial. If withheld until the question of operation was decided it could then be used for the relief of pain as required—not continuously.

Mr. Harrison Cripps said a mild attack might be due to some temporary cause and pass by without operation. But recurrence implied a more permanent condition indicating operation, which unless necessitated immediately should be undertaken in the quiescent period. It was then almost devoid of risk. He had not had a fatal case, and Mr. Treves had had only two in one hundred and thirty operations. The presence of swelling or its absence was not of much significance, as it depended on the position of the appendix. But if there should be very great induration, it might be advisable to wait until the abscess pointed. He objected to buried sutures. He had given up the use of abdominal supports after the operation. He preferred a free incision, and urged the importance of dividing the aponeurosis of the external oblique.

Dr. Hunter held that the disease was always infective; consequently a mild case might at any moment become grave. Suppuration often took place after a mild course of seven or eight days. Therefore he advised operation after that time whenever a rise of temperature occurred. Even 99° or 100° F. might be a significant temperature. Small doses of opium combined with calomel might be useful.

Mr. McAdam Eccles, who had had personal experience of the disease, said the gravity of the case was dependent on the virulence of the microbe. The tissues of the patient could sometimes deal with this, but recurrence should always be met with excision. If they could always remove the appendix the patient would be cured, but this was sometimes impracticable.

Mr. Moullin favored the operation in most cases even at the risk of performing it on patients who might have recovered without. The patient was guaranteed against recurrence by the operation, and its risk was slight. When the symptoms suddenly subsided it might be due to discharge of matter into the intestine, and it was impossible to ascertain the exact condition. Whenever the symptoms were progressing at the end of thirty-six hours an exploratory incision ought to be made.

Dr. L. Thomas, of Cardiff, had had only three deaths in forty-one operations. One case turned out to be a pyosalpingitis, another abscess of the ovary. He had in one instance removed a healthy appendix for symptoms which afterward recurred. They yielded to Weir Mitchell treatment. He used silk for buried sutures, and thought this plan best.

Mr. J. Berry also preferred buried silk sutures, and had never had hernia afterward. The incision should be free and septic matter removed by sponging. He protested against washing out the peritoneum. He had observed that when a surgeon was taken with appendicitis he almost always sent for a physician.

Dr. T. Roberts (president) thought the poor in hospitals had the best chances, as the expense of operations often caused them to be delayed. Physicians were very careful what they did. He was in favor of consultations between physician, surgeon, and family attendant. He thought calomel and opium useful.

Dr. Allchin adhered to the opinion that a great proportion of patients recovered without operation, and one good result of the debate would be that surgeons would no longer oppose the moderate use of opiates.

Mr. Lockwood in reply said rules could not be laid down, for the lesion varied from day to day. A catarrhal mild case to-day might be gangrenous or perforative to-morrow. Several speakers had referred to appendicular abscess. This was almost impossible to diagnose. Why not then make sure by an exploratory incision?

THE TREATMENT OF APPENDICITIS.

To the Editor of the Medical Record.

Sir: Dr. Morris either wilfully or thoughtlessly persists in comparing the surgical plan of operating in every case with the exclusively medical method of not operating in any case, and would have us believe that the conclusions reached from a comparison of their respective results as shown by statistics have some bearing on the question now at issue. If he would only pause a moment and consider the matter without prejudice, he would see at once that statistics giving results of the exclusively medical treatment have no more bearing on the methods which we respectively uphold than would statistics of smallpox or scarlet fever. For purposes of arriving at the right mode of procedure, namely, that which will save the greatest number of lives, the statistics up to date are practically valueless for numerous reasons, the most important being that physicians do not practise the exclusively medical treatment which Dr. Morris tries to make out that I am upholding. Between the extremes of the exclusively surgical and the exclusively medical treatment, though each is advocated by a small coterie of radical surgeons or honest but mistaken physicians, and although there is little to praise and a great deal to condemn in them both, the surgical plan is much preferable, because, as Dr. Morris has well said, the loss of time is less, the death-rate is less, and there is less suffering than under the exclusively medical plan. But we do not accept either of these radical extremes. The vast majority of general practitioners and conservative surgeons have selected the best there is of both the extreme methods, and evolved a plan of management that will cause less suffering, less loss of life, and withal be more practical than either. This plan is to operate on recurring cases as a rule, and to operate on primary cases when circumstances arise which in the opinion of the physician make it justifiable. Dr. Morris asks if I do not know of physicians whom I would not trust to determine the time when operation was justifiable in a given case. I regret to say that possibly there are such, but their number is growing gratifyingly less, and it is not of those I write when I say physicians. I have seen a surgeon operate for appendicitis and remove a handful of stones from a distended gall bladder, but I am not inclined to blame Dr. Morris or surgeons generally on that account. To return to statistics, I wish to admit that I have seen none from Dr. Morris, nor am I able to find that there are any, hospital or any other kind, giving the correct results of the exclusively surgical treatment as compared with the treatment I am obliged to favor. Such statistics in order to be of any scientific value must consist on the surgeons' side only of operation on primary cases. Recurring cases in which the operation is done in the interval belong as much to the general practitioners' side as to the surgical. Again, cases which were mild and treated medically at first until the physician (I mean competent physician) advised operation, and were operated on, whether the operations were successful or not, should be charged to the general practitioners' side; also operations on recurring cases which were treated medically at a previous attack should be credited to our account, if successful, or put on the debit side, if unsuccessful. In other words, the statistics should be made up about as follows:

Surgical.

Dr.	Cr.
Impracticability.	Recoveries from operations on primary cases.
Deaths from operations.	Amount of time saved.
Sequelæ.	

Medico-Surgical.

Dr.	Cr.
Deaths from operations advised by the physician.	Recovery of every case, even the mildest.
Deaths from operations neccesitated by recurrence after apparent recovery.	Recoveries from interval operations.
Sequelæ.	Practicability.

Until Dr. Morris can show statistics on the general plan outlined above, he will do well to drop statistical comparisons which are as unscientific as they are valueless. I believe that a one-per-cent. rate of mortality in cases treated by the medico-surgical plan is none too low when all cases, even the mildest, are included, and unless Dr. Morris can show by statistics carefully arranged, on a plan somewhat like that outlined above, that a one per cent. or one-half per cent. is not a low estimate, it would be well for him to suspend judgment. In order that he may not persist in misunderstanding my position, I will say that the method of management which has commended itself to the profession in general is very concisely outlined in an editorial in the Medical Record of December 30, 1899. Dr. Morris says that he does not know the difference between a mild and a dangerous case of appendicitis, and asks me to define a "mild case." He does not do himself justice in seeking to obscure the real issue by introducing an element entirely foreign to the subject. Every mild case is certainly a dangerous case if it be operated on, and of course has dangerous possibilities if not operated on, but if managed medico-surgically the danger will be reduced to a minimum. Dr. Morris says he does know the pathology of appendicitis. Will he kindly tell us by what term he designates the large number of recorded cases wherein the inflammation was confined to the right iliac region, recovery taking place without formation of pus and no recurrence, and also enlighten us as to the pathology thereof? Dr. Morris asks also if I have actually read those published letters. I most certainly have, and in my opinion they show all the earmarks of a regulation testimonial, as witness letter from patient number six: "No comparison between medical and surgical treatment; the former is torture, the latter painless and blissful results."

Dr. Morris' offer of $1,000 to charity might just as well have been a million as to its results on the treatment he advocates. If he is right the profession will surely find it out, and if his plan is wrong, ten millions of dollars will not blind the eyes of the profession to its shortcomings.

J. S. Horner, M.D.

West Pawlet, Vt.

THE STATIC INDUCED CURRENT.

To the Editor of the Medical Record.

Sir: In his last communication, Dr. Rockwell brings forward no new fact; he merely reiterates pictorially as well as verbally his familiar refrain that, using the apparatus pictured, "the result could be nothing else than the static induced current." Again I repeat, if the result were a current, why did not the ancients say so, and why do they invariably speak of and describe the individual shock which was the purpose for which the apparatus was explicitly constructed? Using gallon Leyden jars with a spark gap of one-twentieth of an inch gives a very painful single shock. And again I repeat that Dr. Rockwell has not yet brought forward the first word to prove that the ancients ever used a series of rapidly passing sparks, thus producing a current, nor has he adduced the least allusion to any sort of a current, whatever its name, nor again allusion to physiological effects upon the muscles such as would be produced by any sort of a current. His entire argument is one of surmise—they might have done so and so.

I reaffirm the title of my article and its contents as true, and no doubt in good time my critic will also be obliged to come to the same conclusion.

Mere captiousness will not down the modern rush of progress in electrotherapeutics or in anything else. Is it, then, indeed so strange to say that one can cure (arrest) locomotor ataxia and arthritis deformans? Is it not to-day common talk and fact to cure phthisis, and yet ten years ago how few would have believed it possible?

But why thresh out old straw any longer; "*Le jeu ne vaut pas la chandelle.*" My one consolation is that it is, after all, no doubt, better to put forth new facts, if done sincerely, even if it does excite a little criticism.

William J. Morton.

March 3, 1900.

Reviews and Notices.

Le Diabète et son Traitement. Par R. Lépine, Professeur de Clinique à l'Université de Lyon. Paris: J. B. Baillière et Fils. 1899.

This book is one of the little booklets of "Les Actualités Médicales" series. All new researches are passed in review. There is a chapter on regimen, and opotherapy is considered.

Les Autointoxications de la Grossesse. Par G. Bouffe de Saint Blaise, Accoucheur des Hôpitaux de Paris.

This is another of the above series, showing how the healthy human organism is a poison factory, the integrity of whose machinery alone prevents the system from being continually injured. During pregnancy the author believes that women run an especial risk of self-intoxication.

Transactions of the Medical Association of the State of Missouri, Forty-second Annual Session. Held at Sedalia, Mo., May 16, 17, and 18, 1899. Kansas City, Mo.: The Burd & Fletcher Printing Company. 1899.

This is a neatly bound volume of papers, many of which are of unusual interest and some of decidedly scientific importance. Dr. Ohmann-Dumesnil contributes a paper on ichthyosis nigricans, showing much literary research.

Handbook of Optics for Students of Ophthalmology. By William Norwood Suter, B.A., M.D., Professor of Ophthalmology, National University, Washington, D. C. New York: The Macmillan Company. 1899.

This work is simplified down to the requirements of the student beginning this branch of science. For those not familiar with trigonometrical ratios, a brief synopsis is given in the appendix. Optics is considered only as it bears directly upon ophthalmology. Heath's "Geometrical Optics" has been made the basis for demonstrating refraction by prisms and spherical surfaces.

Massachusetts Volunteer Aid Association.

This is a report of the work of the association during the war with Spain, when a hospital ship, the *Bay State*, was fitted out and sent to the front. It is interestingly and instructively illustrated. It is compiled by Edward C. Mansfield.

Opinions of Over One Hundred Physicians on the Use of Opium in China. Compiled by William H. Park, M.D. Shanghai: American Presbyterian Mission Press. 1899.

This is a set of questions and answers as to the value of opium and the opium curse, put out in the interests of the anti-opium cause.

Enlargement of the Prostate: its Treatment and Radical Cure. By C. Mansell Moullin, M.D., F.R.C.S. Second edition. London: H. K. Lewis. Philadelphia: P. Blakiston's Son & Co. 1899.

Purely historic considerations have been eliminated, but otherwise there is little change in the present edition. The work is well worth reading by all who have prostatic cases to manage.

Études de Gynécologie Opératoire. By Dr. Phocas. Paris: A. Maloine. 1899.

This paper-covered volume of two hundred and seven pages goes over the ground of operative gynæcology from curettage to total abdominal castration, including clinical observations.

Cure Prompte et Radicale de la Syphilis. Par J. F. Larrien. Third edition. Paris: Société d'Éditions Scientifiques. 1899.

This treatise upon syphilis and mercury, with the author's personal experience with minute doses, has met with a sufficient warmth of reception to necessitate a third hearing. It contains much of interest.

Dermato-histologische Technik. By Max Joseph, of Berlin, and Georg Loewenbach, of Vienna. Berlin: Louis Marcus. 1900.

This is an excellent little work of one hundred and ten pages and nineteen chapters, on the best means of staining, etc., for skin work.

A Manual of Modern Gastric Methods, Chemical, Physical, and Therapeutical. By A. Lockhart Gillespie, M.D. With a Chapter upon the Mechanical Method Used in Young Children, by John Thomson, M.D. New York: William Wood & Co. 1899.

The present work of Dr. Gillespie, who is well known as a specialist for digestive disorders, contains in a succinct form all the methods—diagnostic and therapeutic—used in this branch of medicine. Einhorn, of New York, and Turck, of Chicago, are frequently referred to. The manual is well written and complete, and will be of use to the practitioner.

La Tuberculose est Curable. By Dr. Elisée Ribard; with a preface by Dr. Maurice Letulle. Pp. 170. Illustrated. Paris. 1900.

A book such as this one will always be of considerable interest to the physician, and of positive value to the lay public. In the opening chapter the author shows that tuberculosis in its early stages is curable. The following two chapters—the one devoted to the means and manner of infection, and the other to the early manifestations of the disease—are especially intended for the study of lay people. Under prophylaxis the author indicates the importance of legislative action in preventing the wide spreading of the disease, and in the final chapter on treatment sound and rational procedures are formulated. Altogether the book will repay reading by physicians, legislators, and the general public.

Surgical Suggestions.

Dysmenorrhœa.—Whenever the pain in dysmenorrhœa is entirely or mostly on the right side, especially if it is quite high, it is well to suspect the presence of an appendicitis in connection with the disturbance of the ovary and tube.—A. J. OCHSNER.

Lubrichondrin.—When at a distance from the office, or when a careful, surgically clean assistant is at hand, Professor Bangs' lubrichondrin in collapsible tubes is convenient. But, as the tubes will occasionally "suck back" a little of the lubricant that has been exposed, the whole contents of the tube may become infected.—FERD. C. VALENTINE.

Cancer.—In anatomically impossible cases I do not think it is justifiable to refuse to operate in some fashion, if, after knowing the truth as to the hopelessness of the condition, a patient demands that an operation be done. In these cases the psychical effect of even an imperfect, partial removal of the offensive cancer sometimes is very beneficial, and puts off for months the inevitable morphine syringe which we are compelled to use during the last weeks.—A. C. BERNAYS, *Philadelphia Medical Journal*, November 18th.

Fractures of the Bones of the Leg.—Of 232 fractures of the bones of the leg, 41 were simple fractures of the tibia, 53 were simple fractures of both bones of the leg, 24 were simple fractures of the fibula, 14 were Pott's fracture of the fibula, 17 were compound fractures of the tibia, 7 were compound fractures of the fibula, 71 were compound fractures of both bones, 2 were simple fractures of both bones of both legs, and 3 were compound fractures of both bones of both legs. —W. L. ESTES.

To Avoid the Harmful Effects of the X-Ray from either a static machine or a coil as an exciter one should never have the tube near the patient; it should be two or three feet away when using the fluorescent screen, and should be three feet or more from the plate when taking *x*-ray photographs. Between the patient and the Crookes tube there should always be placed a thin screen of aluminum, which should be grounded by connecting it to the gas-pipe with a proper wire.—F. H. WILLIAMS.

Sequelæ to Herniotomy.—(1) The wound may not unite by first intention, and if the sac has been very adherent the disturbance of the cellular tissue may cause some sloughing. In such cases the wound should be reopened and stuffed with iodoform gauze. (2) Diffuse general peritonitis may set in; this is known by the persistence of the vomiting, the continuance of the pain, distention, and tenderness of the abdomen, with elevation of temperature. This may be due to leakage from a perforation, to a gangrenous condition of the gut, or to the introduction of septic matter from without at the time of operation, as in any other abdominal section. Immediate laparotomy should be done. (3) The reduced gut, which has been returned as suspicious, may become gangrenous and obstruction of the bowel may still continue. If this condition be suspected, the abdomen should be opened and the gangrenous bowel sought for, and either resected or incised, and kept outside the abdomen with the object of forming an artificial anus. (4) The bowel may not be gangrenous, yet be so injured that it may not be able to resume its proper functions, and the patient may die in consequence if not relieved by a laparotomy. (5) The bowel may be temporarily paralyzed by local inflammation so as not to be able immediately to resume its functions, though after some days it may recover completely its normal condition. In such cases there is obstinate constipation, without vomiting or other signs of peritonitis. (6) Cases of acute mania have followed the operation for strangulated hernia, some of which have proved fatal.—SHEPHERD, "American Text-Book of Surgery."

Hemorrhage from the Diploe.—The use of a ten-per-cent. solution of olive oil and beeswax, sterilized, to control the hemorrhage from the diploe, has proved most satisfactory. The wax is pressed into the bleeding surface and allowed to remain.—GEORGE W. CRILE.

Intestinal Perforation in Typhoid.—Operate unless the patient is moribund or not likely to stand the shock. Suture by the insertion of a series of fine silk sutures, after Lembert's method; free the peritoneum of all contamination; close partially, leaving in a gauze drain down to the region of sutures.—WARING.

Intubation is Unsuitable for the following conditions: Obstruction caused by the presence of a foreign body; active ulceration (whether syphilitic or tuberculous) of the larynx; obstruction caused by new growths, whether simple or malignant; obstruction due to pressure by goitre or other tumor of the neck; obstruction by post-pharyngeal abscess.—BERNARD PITTS.

Surgical Hints.—NEVER USE MORPHINE BEFORE ANÆSTHESIA in patients who are in a state of stupor or traumatic shock. In these the drug has a distinct tendency to increase these conditions.—NEVER HAVE ANY MORE ASSISTANTS at an operation than are absolutely necessary. They are apt to get into each other's way, and the more people help you, the greater the difficulty of securing asepsis.—EXCEPTING IN EMERGENCY CASES, every patient about to be operated on is entitled to as careful an examination as if he were applying for life insurance, and to treatment before the operation for any complicating condition.—THERE ARE CERTAIN PATIENTS in whom it is very desirable that they shall make no violent movements while they are being anæsthetized, as for instance in certain fractures. In these cases a full dose of morphine an hour before the anæsthesia will contribute a great deal to secure a quiet etherization.—WHEN USING COCAINE hypodermically, it is seldom necessary to use a solution stronger than one per cent., and then always have the patient in a recumbent position. The danger of cocaine lies in the possibility of syncope from failure of the heart's action, and lying down is the best preventive.—WHEN OPERATING, never put too many instruments in one tray, as it becomes more difficult to find just what you want. It is best to have several small trays, and to put the cutting instruments in one, the artery forceps in another, and the special instruments required in the particular operation you are doing in a third.—DURING THE REMOVAL OF TUMORS having many attachments, it is a good principle to free first all the points that are easily detached, and to pediculate the tumor, as it were, where it is most difficult to free it. This will usually result in the largest vessels being included in the pedicle, so that with your ligature or clamp you may safely secure the most dangerous region, and cut above it without danger.—IN OLD OVARIAN LESIONS, it is often a fact that the patients show a decided insufficiency in the secretion of urea. It is well to subject such patients to preliminary treatment for this condition, for two reasons: The first is that if the proper treatment increases the excretion of urea the patient will have a better chance of recovering from the operation, and the second is that if the patient's urine shows no improvement, the prognosis is rendered more serious, and forewarned is forearmed. —*International Journal of Surgery*, November.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, March 12, 1900.

CHARLES N. DOWD, M.D., CHAIRMAN.

Round Ulcer of the Duodenum.—DR. PERCY BOLTON read this paper (see page 494).

DR. ALEXANDER B. JOHNSON said that his personal experience had been limited, and so far as he knew there had been but three cases of perforating ulcer of the duodenum which had been subjected to operation in Roosevelt Hospital. In one of these, operated upon by Dr. McBurney two weeks ago, the diagnosis was made of an abscess probably originating in the appendix, and evidently an abscess of a good many days' duration. The individual was an elderly man. Unfortunately there was no previous history, and no distinct causation of the disease could be obtained. When admitted to the hospital he was perfectly septic. There was a considerable-sized mass on the right side of the abdomen, situated a little higher than usual for an appendicular abscess, and was evidently localized. The history he gave was that he had been suddenly seized some days previous to admission to the hospital with general abdominal pain. An operation was performed, and a large abscess was found containing a considerable quantity of foul-smelling pus. Further exploration showed the existence of a perforating ulcer of the descending portion of the duodenum and coils of intestines adherent to one another. There was some difficulty in getting to the ulcer, and the condition of the patient put further treatment out of the question. The individual lived five days and died septic. In the second case, operated upon last summer, the symptoms also began without warning on the right side; there was a distinct alcoholic history. This case gave pretty much the same history as referred to as occurring in the Hudson Street Hospital. There was more or less localized tenderness found. The ulcer was a solitary one and situated in the first portion of the duodenum. It was sutured, but the patient did not survive. In a third case, operated upon last April by him, the individual was a healthy, vigorous man, thirty-one years of age. He gave a history of having been upon a prolonged alcoholic debauch for several weeks. He had continued at his work. Three days before his admission to the hospital he was suddenly seized with a moderate pain in the epigastrium, but this did not interfere with his work. He continued to work during the next forty-eight hours, although he was conscious of a certain degree of discomfort. At one o'clock of the morning of the day he was admitted he was awakened from sleep by intense pain in the right side. He then was given an emetic of mustard and water, and vomited. When he entered the hospital his condition was good; there was no fever; he had general abdominal rigidity, more or less marked upon the right side. There was one point of extreme tenderness, situated about three inches above the umbilicus, one and a half inches to the right of the median line. That tender point persisted until the time of operation. The speaker saw him about ten o'clock. The temperature had risen to 101° F. or more, the pulse was almost of normal frequency. The abdominal rigidity and local tenderness were marked. He felt certain that there was present some intra-abdominal lesion, although there was no distention or liver dulness. An incision was made on the right side of the abdomen. The appendix was found to be normal. There was a peculiar appearance of the peritoneal exudate and the contents of the gut. There was considerable amount of fluid, which was bile stained, and contained flocculi of grayish lymph. The diagnosis of a probable perforation of the duodenum was made, and the duodenum was examined. In the anterior portion of the descending part, about where the duodenum disappeared between the transverse colon layers, there was an oval perforation about one-half an inch long and one-quarter of an inch wide. There were no adhesions. From this hole in the gut there was escaping a considerable quantity of dark bile and digested blood. The ulcer was plugged and the entire abdomen washed thoroughly with saline solution; into it was poured hot water in great quantities. The patient suffered absolutely no shock, and he went from the table in as good a condition apparently as he came on. The speaker objected greatly to the evisceration of the abdominal contents, which added so much to the shock. The abdomen was dried and the ulcer was sutured by means of a purse-string suture; this was reinforced by four or five Lembert sutures. The patient recovered without any special complication except a moderate superficial infection in the skin wound. Thirty-eight days after the operation the patient was presented to the Surgical Society. The diagnosis of this condition Dr. Johnson considered very difficult, and one that was very rarely made. He was unaware whether any surgeon in New York had ever made a positive diagnosis or not.

DR. ROBERT T. MORRIS said the subject of suppurative peritonitis was a very important one. Regarding the treatment of the ulcer, it seemed to him that if the ulcer was a small one, without a great amount of serous infiltration of the walls of the bowel, the method employed by Dr. Johnson should be successful. But if the ulcer was a large one, the longitudinal suture, or angulation of the bowel, should be the method of choice. Regarding the matter of general suppurative peritonitis, he believed it was a physical impossibility to remove any large quantities of adherent lymph or serous exudate by washing and stripping the bowels; that procedure he considered to be wrong. In the earlier days the subject of hyperleucocytosis was not understood. If a number of very small incisions were made, if we did not handle the bowel much, if we did not draw the bowel out from the abdominal cavity, then we avoided shocking the patient. If we used long glass tubes, carrying them through various small incisions into the various cavities, and washed out the abdomen with saline solution, so getting rid of the chief toxin-bearing fluid, then we did what was best for the patient. This treatment should be supplemented by distention of the circulatory system with saline solution, using one or two quarts by the intravenous method. Theoretically this caused an evacuation of the fluid by the emunctories, carrying with it the toxins. Distention of the blood-vessels caused a high tension in such cases when there was no hemorrhage, and the evacuation of the fluid certainly appeared to carry off the toxins from the circulation rapidly. The speaker had had several apparently dying patients who had recovered by means of this combined method of treatment. He had two patients in the hospital with flooding of pus from the pelvis to the liver, with pulses of 144 and temperatures of 104° F. at the moment of operation; after operation their pulses fell to 120 and their temperatures to 101° F., and remained there since; he was sure they would get well. He advised that more statistics should be obtained. It was wrong for one man to teach evisceration; wrong to teach filling the abdominal cavity with saline solution, etc., unless statistics proved it to be the better method. The plan of multiple incisions and large intravenous injections should not be advised unless it could be shown to be the best plan of treatment to-day. It was a life-and-death matter to the patient.

Dr. Alexander B. Johnson said he was firmly persuaded that the method of Dr. Morris of refraining from eviscerating the cavity, and washing out by means of Chamberlain's tubes, was a good method of treating extensive purulent peritonitis. Next winter he intended reporting a good many such cases—twelve in number—in which there was quite extensive purulent peritonitis following perforation of the appendix; they were very extensive cases. Several had processes of different types. The treatment employed was precisely the same, *i.e.*, Chamberlain's tubes through small incisions and gallons after gallons of hot sterilized solution thrown into the cavity until the fluid returned clear. Out of this number of patients only two were lost. One died of pyæmia about four or five weeks after the operation. The pyæmia resulted from an abscess situated in a mass of lymphatic glands which lay just above the kidney. The second died of sepsis in spite of irrigation. . In most of the cases that resulted in recovery it was strange that the temperature fell almost to normal and did not again rise. The speaker referred to a patient who had a lesion of the intestine which required suturing. About five days after the operation the patient continued vomiting, and was in such a weakened condition that he thought there was probably a necrosis of the intestine taking place at the site of suture. The abdomen was opened and inspected. In suturing there were pulled out about one and a half feet of small intestine. These one and a half feet of small intestine were as distinctly different from the rest as two things could be; that part which had been outside was dark red and did not react, and was probably paralyzed. The part that was not removed was apparently healthy. The impression made upon the speaker was so strong that he decided he would avoid any extensive handling of the intestines in the future.

Laryngectomy for Carcinoma.—Dr. A. T. Bristow presented this case. The patient was a man, thirty-seven years of age, who first came under observation October, 1899: he then complained of hoarseness which had existed for two years. The growth was intrinsic, and a total extirpation was advised. There was no glandular infection. He was offered the choice between the palliative treatment by tracheotomy, or the possibly curative treatment by extirpation; he chose the latter. Early in 1900 he complained of dyspnœa, a symptom which he had not complained of previously. He was removed to the Long Island Hospital, and a tracheotomy under cocaine anæsthesia was performed. He was then placed in bed and prepared for operation. The teeth were scrubbed every three hours to prevent pneumonia. Nitrous-oxide gas was administered. The speaker considered this the best anæsthetic for the following reasons: It was much less depressing than chloroform, and in a great measure eliminated the danger of sudden death upon the table. It avoided the irritating effects upon the throat and the refrigerating effect upon the lung tissue itself. Again, if the patient showed signs of collapse, the anæsthetic could be at once stopped and the patient was conscious in a very few seconds. This gas prevented vomiting. The technique of the operation was the one described by Keen. The anæsthetic was given through the tracheotomy tube. The larynx was removed entirely with the epiglottis. He noticed that when strong lateral traction was made upon the larynx there was a tendency in the patient to stop breathing. Seventeen days after operation the patient was shown to a medical society. He believed that many cases of cancer of the larynx could be cured by excision if performed early. Glandular infection occurred quite late in these cases.

Dr. D. Bryson Delavan was pleased at the excellent condition of the patient at this early date. He was particularly interested in the views the speaker held regarding the choice of an anæsthetic. It was very desirable that the disease should be recognized early, and early submitted to operation. Partial laryngectomy did not show any more valuable statistics than the complete operation, and the result of the complete extirpation was so much better that there could be no choice between the operations unless the disease was so far advanced that it did not admit any choice. He regretted the failure of many operators to report their cases.

Dr. George E. Brewer said the mortality of this operation was something like fifty per cent., although he thought it would be higher than that if every case was reported. One surgeon had recently stated that if all cases were reported the mortality would be over ninety per cent.; this was probably due to the fact that one was not permitted to operate until the œsophagus and surrounding tissues had become involved. If one could operate upon these patients when the disease was confined to the larynx, the mortality would be much less. Regarding an anæsthetic, he referred to the use of chloroform and oxygen: chloroform was preferred to ether on account of the fact that ether affected the bronchial mucous membrane. This combination had resulted very satisfactorily. He referred to one case of malignant growth; its malignancy was made manifest by the fact that the growth recurred three times in three months; since the last operation the patient was apparently well. He said it was very important in the technique that the areolar tissue surrounding the superior laryngeal folds should be removed, because this removed the lymph channels and so prevented infection.

Extraperitoneal Rupture of the Bladder.—Dr. A. T. Bristow also reported this case, which was a very unusual one. The patient, a woman, aged twenty-four years, fell down-stairs. Forty-eight hours afterward she came under observation. She could pass no urine and was tormented with the desire to urinate. Examination showed a bruise upon the abdomen, and some muscular spasm was present. There were no signs of peritonitis. The house surgeon catheterized her and drew off about two ounces of urine. Six ounces of sterile saline solution was then introduced, and the same amount was recovered. An examination of the urine failed to show the presence of albumin or urea. On the following morning the condition of the patient was about the same; it was not possible to get more than two ounces of urine by means of the catheter. The abdomen was opened in the median line, but no intraperitoneal rupture was found. The peritoneum was closed, and the space of Retz, or retropubic space, was examined, and here urine was found which distended the area between the peritoneum and pelvic cavity. Trendelenburg's transverse incision was made, which gave an excellent exposure of the parts. Air was pumped into the bladder, and a rent in the bladder was found in its antero-lateral wall; the walls were much bruised and ecchymotic. This patient had an extraperitoneal, but not an intraperitoneal, rupture. Such an accident usually occurred in older persons. In a series of ninety cases reported only three existed without fracture of the pelvic bones.

Sarcoma of the Tibia.—Dr. John B. Walker presented this specimen. The patient was a woman, aged fifty-five years, who eighteen months ago slipped and sprained her knee; her physician recognized the condition as one of synovitis, from which she recovered. A few months later, while walking she again slipped and received an injury which also was diagnosed by her physician as a synovitis. The swelling refused to go down. Three months later she was seen by a well known man, who diagnosed the condition as Charcot's joint. A plaster-of-Paris splint was applied with extension, which relieved the pain, but the swelling still persisted. An x-ray photograph was shown. A diagnosis was made of sarcoma, and amputation was performed.

New Instruments.

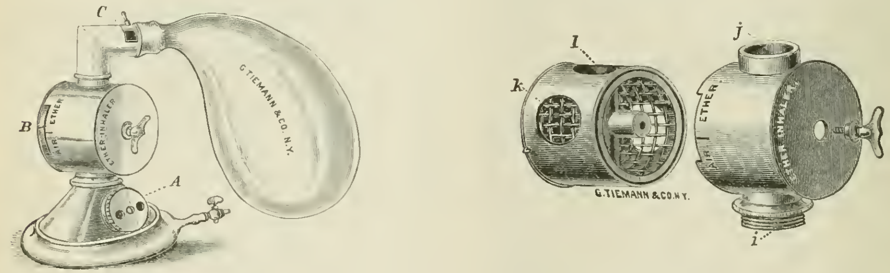
NEW ANÆSTHETIC APPARATUS.

By THOMAS L. BENNETT, M.D.,

ANÆSTHETIST TO NEW YORK HOSPITAL, ROOSEVELT HOSPITAL, ETC.

THE accompanying illustrations represent inhalers for the administration of ether, nitrous oxide, or these agents in combination or succession. They have been devised by the writer after more than ten years of extensive experience in the administration of anæsthetics, during which time many different forms of inhalers have been employed and the principles involved carefully investigated. They have been so constructed as to meet the requirements which have been found essential to the most exact and satisfactory plan of administering the agents in question, and their use in a large number of cases has demonstrated their practicability.

The ether inhaler, Fig. 1, consists of three parts—the face piece, the ether chamber, and the bag. The face piece is cone-shaped; its base is oval and is notched at the nasal end. The apex is open and is threaded to screw into place on the ether chamber. It is of metal, and its free edge is provided with an inflatable rubber cushion, which may be removed at will. On the side of the face piece is an air tap, *A*, which may be opened or closed to any degree. When fully open, this tap has a large capacity—a desirable feature in a bag inhaler.[1]



A. B.

FIG. 1. A, Ether Inhaler; B, Sectional View.

The face piece is made in three sizes—small, medium, and large. The medium size will be found suitable for all ordinary cases, but small children and large men require special sizes.

The ether chamber, shown in the "sectional view," consists of two cylindrical metallic boxes, one fitting accurately within the other. The inner box presents four openings in its sides, two of which, *k* and opposite, are of large size; the other two, *l* and opposite, are smaller and are connected by a tube which passes through the centre of the box. This part of the ether chamber is provided with a cage of coarse wire netting, to hold the gauze which receives the ether. The cage is somewhat smaller than the box it occupies, the intervening space allowing the respired air to circulate freely around the gauze rather than through it, thus offering little or no resistance to respiration. The cage also prevents the gauze packing from protruding through the openings *k* and opposite, and thus interfering with the rotation of the inner chamber. On the closed end of the inner box is placed a revolving disc, presenting a small circular opening at one point near its periphery; this opening is surmounted by a short funnel-shaped chimney, and may be brought opposite any one of three openings in the end of the box. By this arrangement it is possible, when the patient's head is turned on the side, to pour ether upon the gauze without removing the inhaler from the face—a matter of great practical advantage under certain circumstances.[1] The outer box presents two large and opposite openings in its sides, and each of these is surmounted by a chimney, one of which is threaded to receive the face piece, the other being smooth and bevelled to receive the bag. On one side of the free edge of this box is a slot, which, in connection with a pin and pointer on the inner chamber, limits the rotation of the latter and indicates whether "air" or "ether" is being breathed. When the two parts of the ether chamber have been put together, they are held in place by the thumb-screw shown in the drawing, and this serves the further purpose of a handle for revolving the inner cylinder.

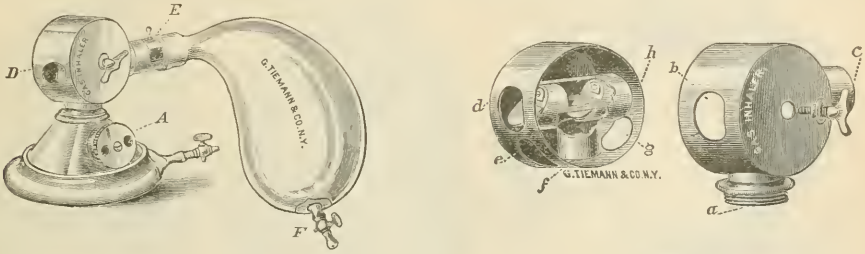
By referring to the sectional view of the ether chamber, it will be seen that a tube traverses the centre of the inner cylinder, its upper opening being marked *l*. Now if the two parts are put together in the positions they occupy in the cut, it is evident that the openings of the tube *l* will correspond with those marked *i* and *j* of the outer cylinder; and if breathing should take place through the inhaler so arranged, the air would pass directly through the tube *l* without entering the ether space proper. In this position it will also be noticed that the index pointer, seen directly below *k* in the "sectional view," occupies the lower end of the slot on the outer cylinder, indicating "air." If the inner cylinder is now rotated so that the index traverses toward "ether," it will come to a transverse line between "air" and "ether," and in this position the openings of the tube *l* are just beginning to pass out of the openings *i* and *j*, and the openings *k* and opposite are beginning to enter the openings *i* and *j*. Breathing through the inhaler in this position allows a very small percentage of air to pass through the ether space; further rotation increases this percentage, till finally the tube *l* has passed completely away from the openings *i* and *j*, and full ether is on, the index pointer being at the upper limit. In this way the ether may be turned on as slowly as desired, and any strength of ether vapor may be administered at will throughout the narcosis.

---

[1] In this respect the Ormsby apparatus is usually inadequate, the tap being too small, and in Clover's there is no air tap.

[1] In operations about the head or neck it is often desirable to cover the inhaler and the hand and arm of the anæsthetist with a sterile towel. Under these circumstances it is inconvenient to disarrange this every time it is necessary to add ether, and it was for this class of cases in particular that the arrangement was added. When this plan of adding ether is to be used, the inhaler should be so applied to the face that the revolving disc is uppermost.

The ether bag, shown in Fig. 1, A, is of large size, its capacity exceeding the most exaggerated respiration. It is attached to an elbow of metal tubing, by which it is connected with the upper chimney of the ether chamber when in use. In this elbow, near the attachment of the bag, is a large air tap, *C*, which may be opened to any degree.



A.

B.

FIG. 2.—A, Gas Inhaler; B, Sectional View.

The use of the ether inhaler may be briefly described as follows:[1] The wire cage is packed firmly with dry gauze, upon which one-half ounce or more of ether is poured; the index is now turned to "air," the taps *A* and *C* are closed, several expirations are caught to distend the bag, and the face piece is then kept applied; the index is now turned to the line between "air" and "ether" and is moved forward slowly toward the latter, an occasional breath of air being given by removing the face piece. Complete anæsthesia is present in from two to five minutes in average patients. The administration now consists chiefly in the regulation of two factors—the ether supply and the air supply.

The ether supply: In continuing the administration, it is best to allow the index to remain at full ether and to pour from one-half to one drachm of ether upon the gauze every two or three minutes as necessary. This may be done (1) through the face piece, (2) through the chimney, or (3) through the revolving disc on the end of the ether chamber; (1) is preferable in usual cases; (2) or (3) is of great advantage when it is inconvenient to remove the inhaler from the face.

The air supply: During the induction of anæsthesia enough air should be given to prevent more than slight cyanosis. In maintaining anæsthesia it is rarely necessary to exclude air to the extent of causing any cyanosis, and the air supply is to be regulated in accordance with the following facts: The tap *C* (Fig. 1) being closed, if *A* is opened slightly the patient will receive little air and much ether; if fully opened, he will receive much air and little ether. The tap *A* being closed, if *C* is opened slightly the patient will receive little air and much ether; if fully opened, he will receive much air and much ether.

The quantity of ether necessary in usual cases will average about four ounces for the first hour and about two ounces for the second hour.

The gas inhaler, shown in Fig. 2 and in the "sectional view," consists of three parts—the face piece, the valve chamber, and the gas bag. The face piece is identical with that of the ether inhaler, and is made in three sizes—small, medium, and large.

The valve chamber consists of two cylindrical metallic boxes, one fitting accurately within the other. The inner box contains a T of tubing, the longer or cross part of which traverses the centre of the chamber and is joined in the middle by the shorter or stem part of the T. The three ends of this T open upon the outer surface of the sides of the box. The longer of these tubes contains the valves mounted upon a skeleton tube, which may be removed at will. The valves themselves consist of thin rubber flaps, fastened at one end over fenestrated diaphragms set in an inclined position in the skeleton tube. Each rubber flap is reinforced by a thin piece of aluminum cemented to its surface. This keeps the rubber flat and prevents it being forced through the opening it guards, during violent respiration.[1] On each side of the opening of the short or stem part of the T above described is placed a similar opening communicating with the general box cavity.

The outer box presents three openings through its sides, two of which are provided with chimneys. One of the latter has a thread cut upon it for the screwing on of the face piece. The other is slightly bevelled for the twisting on of the gas bag.

The boxes are held together by a thumb-screw, which also serves as a handle for rotating the inner chamber, the rotation being limited by a slot on the outer box and a pin on the inner.

The gas bag is of pure rubber, and has a capacity of about two gallons when just full, but will distend to several times this capacity without bursting.[2] It is attached to a short metal tube, the free end of which is ground to fit the smooth chimney of the valve chamber. In this tube is placed a large air tap, shown at *E* in Fig. 2, A, which may be opened or closed by a lever. Working in connection with this air tap is a cut-off, placed between the air tap and the bag, and so arranged that when the air tap is fully open the gas is completely cut off and confined to the bag. When the air tap is closed the bag is opened into the tube. At the opposite end of the gas bag is a hard-rubber stopcock, through which the gas is admitted to the bag. By referring to the sectional view of the gas inhaler, it is apparent that if the two boxes are pushed together in the positions they occupy in the cut, the face piece screwed on at *a*, and the inhaler breathed through, during inspiration the valve at *d* will close, so that the air must enter through the chimney *c*, pass through the valve at the opening *h*, and down through the opening *f* into the face piece. During expiration the valve at *h* will close and the air must pass into the T and out through *d* and *b*, which are now together. The inhaler is used in this position in the ordinary administration of nitrous oxide. By revolving the inner box so that *d* is depressed and *h* elevated to the limit allowed by the pin and slot above referred to, the opening *b* will be closed and *e* and *g* will come together with *a* and *c* respectively. Breathing now takes place through the box cavity, the valves are out of action, and both inspiration and expiration pass through the opening *c*. This position is used for a short time during the administration of "gas and ether."

---

[1] The plan of administration here described is termed the "close method," inasmuch as more or less exclusion of air is practised. Those who prefer the "open method" need only omit the bag.

[1] These valves may be replaced when necessary by cutting pieces of rubber bandage into proper shape and cementing the aluminum forms to them.

[2] A very practical point in view of the fact that such over-distention is common from inability or failure to turn off the gas in time, or from unexpected rushes of gas from the cylinder. Under these circumstances bags made from non-elastic material must burst, and this is a matter of alarm from the loud report, failure of the narcosis from inability to proceed, and expense from having to replace the bag.

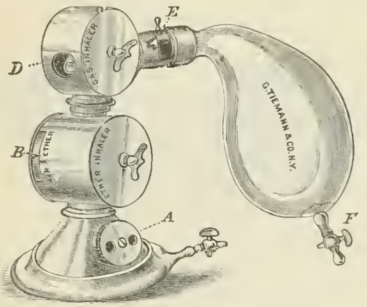


Fig. 3.—Inhaler for Gas and Ether.

The use of the gas inhaler may be briefly described as follows: The tap *E* being fully opened, the bag is filled moderately full of gas from the cylinder through the rubber tube supplied with the inhaler. The aperture *D* should be fully open. The face piece must fit the face perfectly. Inspiration will now enter at *E* and expiration escape at *D*. Upon closing the tap *E*, gas will be drawn from the bag on inspiration and escape at *D* on expiration. As soon as the inhalation begins, a flow of gas sufficient to keep the bag moderately full should be turned on from the cylinder. The inhalation should be conducted according to the principles of gas administration. Air in any quantity may be admitted through the tap *E*.

For "gas and ether" the inhalers are combined as shown in Fig. 3, and are used as follows: The ether inhaler is charged with ether, the index turned to "air," and the tap *A* closed. The gas inhaler is firmly attached to the upper chimney of the ether inhaler, the apertures *D* and *E* being wide open. The bag is filled with gas and disconnected from the tube at *F*. The face piece is accurately applied to the face, and *E* is closed. Gas is now breathed through the valves, and when the bag has been about three-fourths emptied *D* is to be closed. Gas is now breathed back and forth, and at this time the patient will be unconscious or nearly so. Ether should now be turned on gradually, though somewhat faster than when it is given without gas. The patient is now breathing gas and ether, and in about one minute from the beginning of the administration will show signs of complete gas anæsthesia if the face piece has been tightly applied.[1] It is unnecessary, however, to push the gas beyond the approach of these signs, upon which air should be admitted at *E* for two or three respirations. After a few more respirations of gas and ether, the gas inhaler and bag are removed, the ether bag is substituted, and ether is pushed to complete anæsthesia. This is accomplished in from two to five minutes as a rule, and usually without the least struggle or excitement, the patient having no knowledge of the ether.

These inhalers have been made as small and as simple as possible, in view of what they have to accomplish. They can be taken completely apart with great ease, and are capable of being thoroughly cleaned and sterilized. The only part of the inhalers that should not be boiled is the tube carrying the valves of the gas inhaler, which may be sterilized by soaking in carbolic solution. Before boiling the face piece and bags, they should be removed from the metal parts and the hard-rubber stopcocks taken out.

Fresh gauze packing should be used for every case. The inhalers should be handled carefully.

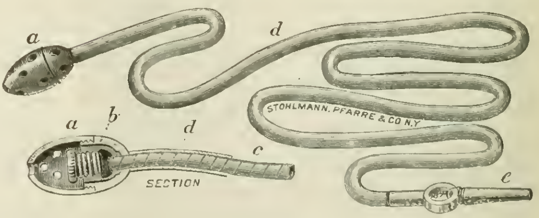
The successful working of these inhalers depends upon the accuracy with which many details of construction have been carried out, and while this has been well done by the makers, it has been found that from a practical clinical standpoint individual inhalers are apt to require certain corrections before they are perfect. For this reason the writer has arranged to examine each inhaler as soon as it is made, and when it is found perfect will issue a certificate to that effect. These will accompany the inhalers, each of which is designated by the number stamped upon it.

A MODIFIED EINHORN GASTRIC ELECTRODE.

By GEORGE ROE LOCKWOOD, M.D.,
NEW YORK.

The passage of the original Einhorn electrode into the stomach has, in my experience, proved an unpleasant if not impossible task for the great majority of patients. The large size of the capsule renders difficult the primary attempt at deglutition, and even after the capsule has actually entered the œsophagus the necessity of its dragging a long tail after it naturally impedes its progress.

To obviate these difficulties the following modification has been devised: The capsule (*a*) has been reduced in size to that of an ordinary five-grain gelatin capsule, as is shown by the cut. To the metal point (*b*) within the capsule is attached a spiral of flat steel (*c*), the flexibility of which corresponds to that of an ordinary stomach tube. This spiral is covered by thin rubber tubing (*d*), and is tipped by a binding pin (*e*) for connection with the battery. The spiral with its rubber sheath is of the diameter shown in the cut.



Such an electrode can be easily introduced into the stomach without discomfort. The small size of the capsule allows of its ready passage, while the spiral attachment is sufficiently resistant to enable the operator to push the capsule along, just as a stomach tube is introduced. The result of such modifications has been so satisfactory that no further excuse is offered for the presentation of the instrument.

The patient is the only one who will not trust you when you say you "don't know."

---

[1] The signs that accompany complete gas anæsthesia are cyanosis, jerky, snoring respiration, twitching movements in the extremities, and loss of reflexes.

A NEW, SIMPLE OPHTHALMOSCOPE.

By CHARLES H. MAY, M.D.,
NEW YORK,
CHIEF OF CLINIC, EYE DEPARTMENT, VANDERBILT CLINIC, AND INSTRUCTOR IN OPHTHALMOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY, NEW YORK.

THE features of this ophthalmoscope (Figs. 1 and 2) are simplicity, compactness, excellent mechanical and optical construction, including accurate stops, perfect lenses, proper balancing, and reasonable cost; an important improvement consists in the regulation of size of the various openings, so that there is a minimum of annoying reflex from this source.

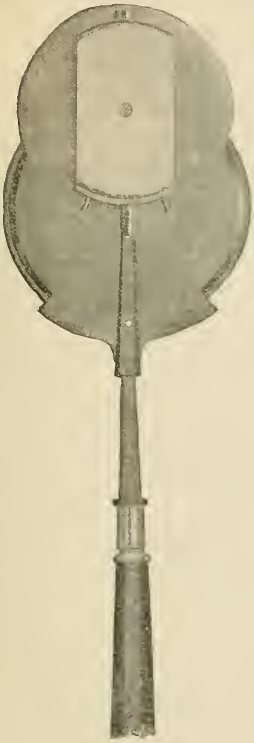


FIG. 1.

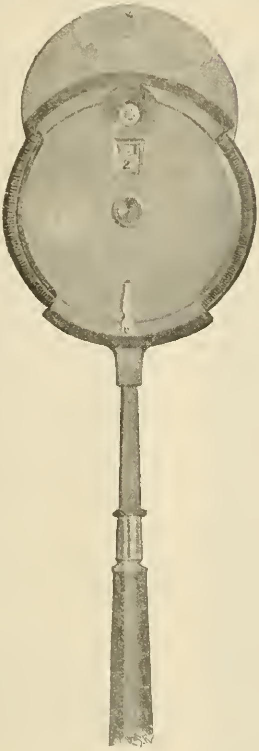

FIG. 2

The instrument consists of two superimposed plates —the front disc, 43 mm. in diameter, holding the convex; the rear disc, 41 mm. in diameter, containing the concave lenses. There are fourteen lenses in each set, the weaker ones being separated by half-diopters, as follows: 0.50 D., 1 D., 1.50 D., 2 D., 2.50 D., 3 D., 4 D., 5 D., 6 D., 8 D., 10 D., 12 D., 15 D., and 20 D., + and − respectively. A greater variety of lenses can be obtained by combinations, but it is not intended that they be employed in this manner, the number when used singly being sufficient for all purposes. The convex lenses are numbered in white, the concave in red, as in most instruments of American manufacture. The strength of the lens in use is shown in an opening in the rear plate.

The two discs can be moved independently of each other, with ease and certainty, through the following arrangement: The disc holding the convex lenses is slightly larger than its fellow, placed in front, and only its extreme edge is milled; the disc containing the concave lenses is slightly smaller, placed behind, its margins are thickened, and the milling of its edge is carried a short distance over the posterior aspect. The index finger should be applied to the lower part of the milled edges, thus avoiding contact with the face of the patient. The finger is placed upon the projecting front disc edge, or more posteriorly upon the rear disc edge, according to whether + or − lenses are desired.

The tilting mirror, concave, of the usual focal distance, is made of very thin glass, and has a 2.5 mm. aperture, the margins of which have been thoroughly blackened; it is supported upon a metal plate with a central defect of 7 mm. The opening of the back plate (sight-hole) is 4.5 mm. in diameter, bevelled 2 mm., so as to present a sharp edge. The lenses are 6 mm. in diameter and accurately centred. The opening in the front plate is 6.5 mm. in diameter, with a 2 mm. bevel. Thus all the openings are larger than those of the mirror and sight-hole—an arrangement which reduces to a minimum the annoying cloud-like reflex so frequently found in ophthalmoscopes.

The handle of the instrument is octagon, and the joint is square, on section, instead of round; both of these modifications contribute to easier and firmer grasp. By the introduction of the requisite amount of metal, concealed in the handle, the ophthalmoscope is properly balanced and not top-heavy; its entire weight is two ounces.

The instrument is supplied in the usual leather box with a biconvex lens of good size, or merely with a soft leather case for protecting the upper part. It is manufactured by W. T. Georgen.

The writer desires to express his appreciation of the manufacturer's courtesy during much experimental work and his painstaking execution of successive models.

Leprous Fever is essential and due to the bacillus or its toxins. It is always intermittent, if uncomplicated. It may occur at any period including the prodromal. It probably occurs in all forms in varying degree. When fever of a continued type is observed, it is due to the presence of other toxins acting either with or entirely apart from those of the bacillus lepræ. The essential fever simply shows that the disease is active and progressive.—ALEX. LEWERS, *British Journal of Dermatology*, October, 1899.

Scoliosis and Nervous Affections.—H. Oppenheim says that scoliosis is most common in syringomyelia and sciatica; lateral curvature is also observed in dystrophy and acute anterior poliomyelitis. Spastic conditions of a primary or reflex nature (pain) may also cause it; hysteria and traumatic neurosis may also give rise to the condition. Spastic infantile hemiplegia, diplegia cerebralis, congenital athetosis, and chorea occasionally produce it. Hemiplegia spinalis may give rise to it, and paralysis agitans rarely causes a severe grade of scoliosis. One theory of its causation is based upon a trophic disturbance of the osseous and ligamentous structure of the vertebral column, the other upon a paralysis and atrophy of the muscles of the back. Scoliosis of a severe degree may, by purely mechanical means, cause a neuralgia. Scoliosis may be congenital or acquired very early in life; in fact it may be transmitted from one generation to the other.—*Deutsche Aerzte-Zeitung*, January 15, 1900.

Medical Items.

Red Gill is reported to have attacked the bivalves of Chesapeake Bay. Red or "bloody" oysters, while they are not supposed to be especially harmful, are scarcely marketable. The red color is thought to be due to iron or other mineral in the water. Southern oysters are reported to be unusually scarce this season.

Regarding the Production of Uric Acid.—J. Weiss (*Zeitschr. f. physiolog. Chemie*, xxvii., 3, p. 216) contributes the results of his continued experiments with cinchonic acid as a factor in the production of uric acid. He proves that the ingestion of cinchonic acid, even in those cases in which special feeding was resorted to in order to increase the excretion of uric acid, was always succeeded by a decreased production of the latter. He concludes that the only way in which the uric-acid production can be increased is by proper feeding (such as with thymus, pancreas, etc.). Neither drugs nor the ingestion of uric acid itself or its prototype glycocol will produce the same result.

The Treatment of Leprosy with Antivenene.—Woodson (*Philadelphia Medical Journal*, December 23, 1899, p. 1231) has reported a case of leprosy in a woman, thirty-six years old, the diagnosis being confirmed by microscopical examination, in which marked improvement followed employment of the antivenene of Calmette. The serum was injected subcutaneously, as a rule in the interscapular region, in the loose tissues below the margin of the ribs, and in other selected regions. The dose varied from 33 c.c. at first to 20 c.c. at the close of the treatment. Besides, large doses of hoang-nan were administered. During the three months covered by the treatment, 500 c.c. of serum were administered in forty-seven injections. As a result of the treatment the patient was much improved, having lost her leprous expression and the infiltration in various parts of the body disappearing. The bluish color of the face changed to a healthy red. Some ulceration that was present disappeared, together with a number of tubercles. Anæsthesia that was present subsided, and the skin became softer and fairer. The patient gained fourteen pounds in weight

The Diagnosis of Adrenal Growths.—In Henry Morris' article on primary tumors of the suprarenals and their removal by operation (*British Medical Journal*, November 11, 1899), the author has the following to say about diagnosis: Granted that in any given case there is the following group of symptoms, the diagnosis of a primary adrenal new growth should be made, and will most probably be correct: 1. A tumor in the suprarenal or renal region with a kidney-shaped prominence on the surface of the tumor. 2. An unusual degree of motility of the tumor, so that it falls away from the loin on the patient rising or turning on to the opposite side. 3. Rapidity of growth of the tumor, and secondary growths in the skin, liver, or the temporal region. 4. Marked emaciation and rapid loss of strength. 5. Absence of any change in the urine, and of any alteration of the normal temperature. 6. The presence of some pigmentation of the skin, or of marked or rapid growth of hair over the body. 7. Some gastro-intestinal symptom, such as nausea, vomiting, diarrhœa, or constipation. 8. Pain, deep seated in some part of the abdomen; or an ill-defined, unexplained pain in some joint or distant part of the body. It is, however, the exception to find the whole, or even the majority, of these symptoms present in any given case. If several of them are absent, and most especially if there is no tumor, a positive diagnosis is quite impossible.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended March 17, 1900:

		Cases.	Deaths.
SMALLPOX—UNITED STATES.			
Alabama, Mobile	February 24th to March 10th	11	
Florida, Jacksonville	March 3d to 10th	2	
Indiana, Evansville	March 3d to 10th	5	
Kentucky, Covington	March 3d to 10th	6	
Louisiana, New Orleans	March 3d to 10th	79	22
Michigan, Detroit	March 5th	12

MUSCULAR RHEUMATISM.

BY I. ADLER, M.D.,

PROFESSOR OF CLINICAL PATHOLOGY, NEW YORK POLYCLINIC; VISITING PHYSICIAN TO THE GERMAN HOSPITAL; CONSULTING PHYSICIAN TO THE MONTEFIORE HOME FOR CHRONIC INVALIDS.

PERHAPS there are few subjects in medicine on which more has been written than on rheumatism. Many endeavors have been made to reach an understanding of the morbid processes involved in this class of diseases, by clinical analysis, by anatomical and even experimental investigation, but as yet without complete success. It has not yet been possible to formulate either anatomically or clinically sharply defined types, nor has any one of the theories propounded succeeded in obtaining universal assent. Indeed, rheumatism, and especially muscular rheumatism, is still more or less a sort of diagnostic scrap bag, into which one is accustomed to throw promiscuously all those ailments accompanied by pain and which cannot conveniently be otherwise classified. Authorities still differ widely as to what is meant by muscular rheumatism, and what is the nature of the lesions which underlie its manifestations. In the first half of this century earnest efforts were made, especially in France, to arrive at an anatomical understanding of the rheumatic affections, and with that object even experimentation upon animals was resorted to, especially by Gendrin. In this manner the theory of rheumatic inflammation of muscles was gradually evolved, though, of course, curiously interwoven with the reigning humoral dogmas. On this basis Froriep finally elaborated the whole subject in his often-quoted book, "Die rheumatische Muskelschwiele." There is no doubt that Froriep describes as rheumatic inflammation and induration many conditions which to-day are known to depend upon altogether different lesions and to belong to quite different groups of diseases. But the book contains nevertheless much that is well worthy of attention even in our time. In 1847 Virchow finally gave a detailed and exhaustive anatomical and histological description of rheumatic inflammation of the muscular tissue, which, with some modifications, remains in full force to-day. On the other hand, the majority of clinicians and practitioners has at all times looked upon rheumatism less from the anatomical than from the etiological point of view, subject to the dominant theories of the time. Besides all sorts of morbid humors and diatheses, exposure to cold and draughts, the influence of weather, chill and damp, were held responsible and dominated the whole subject of rheumatism perhaps to a greater extent than any other department in the whole field of medicine. Even to this day opinion differs as to whether muscular rheumatism is dependent upon structural lesions or is merely functional. The very latest writer on this subject, Lorenz, in Nothnagel's "Handbook," defines muscular rheumatism, or, as he prefers to name it, "myalgia rheumatica," as follows: "Those diseases in which muscular pain is the prominent symptom, and as a consequence of the pain functional disturbances and even obstinate contractions are brought about, but which depend upon no structural lesions, and during life, with the exceptions of the contractions, offer no palpable objective symptoms, and which are due etiologically to cold (*Erkältung*)." This view of muscular rheumatism is probably at the present moment the one that is most generally accepted, though there are some notable authorities who differ in several essential points. It is not my intention to give a detailed and critical review of the literature on this subject. I propose merely to summarize in brief the convictions which have impressed themselves upon me in the course of years as the result of a careful study of the literature and abundant observation, in part on my own body. It will be noticed that the conclusions arrived at are in every point the exact opposite of those formulated by Lorenz.

It may be summarily stated at the very outset that the anatomical lesion underlying every case of muscular rheumatism, acute or chronic, is an inflammation, not necessarily altogether confined to the muscle, as will be shown later, but as far as the latter is concerned an interstitial inflammation. Muscular rheumatism may therefore quite generally be designated pathologically as a myositis interstitialis. This is the view held by many of the older authors, and especially urged by Virchow, and, it is believed, is entirely corroborated by all modern experience and investigation. I cannot here present any anatomical material. It is obvious that the difficulties of procuring proper anatomical material for adequate histological research are very great. People do not die of muscular rheumatism, and while it will subsequently be shown that it is very easy to demonstrate the myositic patches in the living, it is indeed wellnigh impossible to find such patches in the corpse. It is no doubt owing to this difficulty that our knowledge of these forms of myositis, especially of the finer histological detail, is still extremely and embarrassingly imperfect and incomplete. Without that, however, thanks to occasional excisions of diseased muscles in the living subject, and to opportune and lucky finds in the corpse, enough material has from time to time been available to enable us to arrive at some idea of the actual pathological conditions on which these muscular lesions are based. It is, moreover, possible to approach the subject experimentally. It is not difficult to produce in animals parenchymatous as well as interstitial muscular inflammation. The study of these lesions lends valuable assistance in the interpretation of the clinical observations. Lastly, it is permissible, with due precaution, to bring to bear upon our subject the result of histological work done upon other forms of myositis, which, while in many respects closely analogous to rheumatic inflammations, are more easily accessible and have therefore been more minutely studied. I refer particularly to the septic form of myositis, and to syphilitic interstitial myositis, especially as occurring in the heart.

Guided by these lights we may conceive the rheumatic process in muscles as follows: In one or more places of the muscular system hyperæmia with dilatation of the smaller vessels and capillaries, sometimes even accompanied by small hemorrhages, takes place.

This is at once followed by a more or less copious emigration of cells into the interstitial tissues, the leucocytes crowding between the bundles of fibres and even between the single fibrils. Very soon active proliferation of the interstitial connective tissue takes place, and thus in a comparatively very short time after the beginning of this process an infiltration of the muscle is brought about, which varies in extent and density according to the intensity of the process. During all this time the muscle fibres themselves are not very materially affected; they are pushed apart to some extent, but do not greatly suffer. In the milder type of cases the process ends here. In due time, usually after but a very few days, absorption of the infiltrating material takes place. The muscle returns to a condition practically, though perhaps never quite, normal. If, however, the inflammatory activity attains a higher grade of intensity, the process does not end with the mere cellular infiltration and at most a very slight degree of connective-tissue proliferation. More extensive new formation of fibrous tissue is inaugurated, sometimes to quite a considerable degree. The interstitial connective tissue proliferates vigorously; the muscle bundles and fibrils have been forced apart and compressed. They also begin to degenerate and are destroyed, exactly in the manner described for interstitial myocarditis. The result of this is a fibrous induration of the muscle. It is evident that when this stage of fibrous induration has been reached, spontaneous restitutio ad integrum is no longer possible. If left to itself, the induration will remain, impeding function, causing pain, and facilitating the recurrence of other acute attacks, thus leading over from acute to chronic muscular rheumatism.

In rare cases the indurative proliferation proceeds still further. Hard fibrous tissue is formed to a considerable amount. The muscular tissue is extensively destroyed. There results from this a white, hard, cicatricial mass of tissue in which the microscope can detect only occasional solitary remnants of degenerate muscular fibres, and which, in its general structure, closely resembles tendinous tissue. This is the genuine "Muskelschwiele." Before proceeding further it is well to emphasize the fact that what is usually termed muscular rheumatism is not necessarily confined to muscular tissue alone. It is of common occurrence that in cases of articular rheumatism the muscles in the immediate vicinity of the joint are also affected, and vice versa, that in muscular rheumatism the nearest joints also suffer, though usually but very slightly. But aside from articular affections it is a fact easily verified that the inflammatory process is, as a rule, not limited to the muscle, but involves the adjacent tissues as well: the fasciæ, tendons, the subcutaneous, fatty, and cellular tissue, and particularly—and this is perhaps not sufficiently recognized—the nerves. A typical rheumatic neuritis (sciatic, median, radial, etc.) has long been recognized, in which interstitial inflammatory processes, similar to those described in the muscles, are at work in the neurilemma. But aside from this typical neuritis of the larger nerve trunks which occurs as an independent rheumatic affection, it is safe to say that in most cases of rheumatic myositis more or less numerous larger and smaller nerves of the immediate neighborhood are also involved in the process of interstitial inflammation. It will be seen that not a few of the clinical symptoms associated with muscular rheumatism find their explanation in this affection of the nerve supply.

If the foregoing anatomical statements are based upon facts, if muscular rheumatism is in truth a localized inflammation associated with infiltration and swelling of the tissues involved, we might justly expect to be enabled to recognize these infiltrations by clinical examination, that is to say, by palpation. This is indeed true for every case. Scattered communications by various authors here and there (Opoltzer, Ewer, Lacquer, etc.) have repeatedly called attention to circumscribed patches of swelling and infiltration that could at times be felt in rheumatic muscles. These statements, however, have either been simply put aside as based upon error, or else the swellings have been accepted as an exceptional and unexplained occurrence, or else interpreted as the expression of partial muscular contraction. It is a particular merit of the masseurs (Metzger and his pupils, Helleday, Nostroem, Schreiber, and others) to have zealously directed attention to these conditions, though perhaps without adequate anatomical substantiation. But notwithstanding all that has been said and written about these things, notwithstanding the universally lauded success of Metzger in the treatment of these muscular affections, the great majority of practitioners have kept entirely aloof and have persistently ignored all advance in this direction. With some practice in palpating muscles, and after attention has once been directed to these muscular lesions, it is not very difficult to convince one's self of the existence of these infiltrations, indurations, and swellings in every case of muscular rheumatism. It must be borne in mind, however, that the infiltration is not necessarily found in the spot to which the patient refers his pain, and recalling what was said above with regard to the participation of the nerves in this process, this will not appear surprising. Take, for example, one of the most common forms of muscular rheumatism, the so-called lumbago. In some cases this is strictly localized, and the pain is referred to the precise spot where on examination the muscular infiltration is found. In other cases it is said by the patient that the pain is "all across the back," or radiates into the abdominal wall down to the groin. A superficial examination of the dorsal and abdominal muscles will in such cases fail to detect any lesion. Indeed, all these muscles are probably entirely sound, and it is no doubt that from such cases and from such examinations the conception of "myalgia without anatomical lesion" has been derived. Nevertheless a more careful palpation will without fail demonstrate in some one muscle or in several at the back, perhaps the gluteus, perhaps the quadratus or the spinalis longus, one or more, sometimes quite small areas of infiltration which are extremely sensitive to pressure, and from which the pain radiates in all directions along the track of larger and smaller nerves, and is referred, as is the case with every nerve pain, to the periphery of the nerve affected. The infiltration varies greatly in size, shape, and consistency according to the extent and intensity of the inflammatory process. It is impossible in very acute cases, on account of the intense pain produced by the slightest touch, to palpate the diseased muscle with exactness. After subsidence of this acute and violent stage, the infiltrations may be recognized by careful palpation in various forms of configuration. They may be round, fusiform, or flat. The surface may be smooth or somewhat broken and uneven. They may be quite hard and firm, or rather soft and doughy. It is to be noted also that, while normal muscles react upon a certain vigorous grip with a contraction of the part touched, the diseased muscular tissue will either not react thus at all, or with plainly diminished vigor. The diseased parts of the muscles appear besides distinctly less elastic than the normal. After the acute inflammatory stage has passed, the muscle, as a rule, resumes its functions without pain or any subjective inconvenience. Nevertheless, palpation of the diseased and infiltrated area even then is without exception quite painful, and this sensitiveness to touch is of great service in detecting the foci of the lesion. When examining for these muscular lesions it is necessary to compare the suspected area with the corresponding place on the other side. Aside from differences in consistency, elasticity, size, etc., it will be found in every case that the diseased portion is sensitive to a degree of pressure which is not at all painful at normal places. A thorough appreciation of these facts and a sense of touch developed and educated by practice will enable us to demonstrate muscular infiltration or induration in every case of muscular rheumatism without exception. More than that, it will very often be possible by the detection of such diseased areas in muscles and their vicinity, to arrive at a correct interpretation of entire groups of symptoms past and present, especially in cases in which the acute initial stage was very mild and has passed entirely from the recollection of the patient, thus affording us no anamnestic data whatsoever.

The clinical picture presented by muscular rheumatism varies according to the intensity and extent of the process, and according as it assumes an acute or chronic character. There are cases which convey altogether the impression of acute infectious disease and are accompanied by fever, seldom, it is true, above about 102° F., but in exceptional cases rising to 104° F. and over. The muscular swelling extends in these cases over a considerable area, the cutis is tense and shining, and the slightest motion or touch causes almost intolerable agony. Even when the diseased parts are entirely immobilized and protected from all harmful influence, very severe spontaneous pain is as a rule present. In these cases the disease usually affects a number of muscles lying in more or less close vicinity, but is, as a rule, confined to one region alone. We rarely see this acute and intense affection appearing simultaneously in different regions of the body. Very often, too, the joint nearest to or surrounded by the diseased muscle is also somewhat, though possibly but very slightly involved in the inflammatory process. This corresponds to the generally recognized fact that in acute articular rheumatism the muscles adjoining the diseased articulation are also more or less inflamed. This form of muscular inflammation which appears in the train of acute or chronic articular rheumatism is considered by some authors as the true and only myositis rheumatica. This view is entirely unfounded, inasmuch as these forms of muscular inflammation differ in no essential respect from the form of interstitial myositis as typical for the ordinary muscular rheumatism. Another feature in these acute cases of muscular rheumatism which suggests very vividly infectious disease is the not infrequent occurrence of endocarditis and of cutaneous lesions, petechia, erythemata, and urticaria, the so-called peliosis rheumatica.

Another group of cases presents an entirely different type. I include under this heading those forms of muscular rheumatism which are usually of short duration, more transitory in character, extending over a very limited area of tissue, and which, while at times appearing in various and widely distant regions of the body simultaneously, may, on the other hand, cling obstinately to one spot and occur again and again always in the same place. Such affections are the common lumbago, the rheumatic caput obstipum (*vulgo* stiff neck), certain forms of intercostal pains, usually designated as intercostal neuralgia, but in fact nothing else than rheumatic myositis of the intercostal muscles, and similar affections in the various muscular groups all over the body. These affections are so well known and of such frequent occurrence that the mere mention of them would appear sufficient. There are nevertheless some points in this connection which are not generally recognized and are of some importance. The first is the question of fever. The general conviction is that these mild and strictly localized cases of muscular rheumatism are not associated with rise of temperature, and it is undoubtedly true that in many cases there is no fever. Nevertheless Leube's statement that in very numerous instances, even in these mildest cases, there is a slight rise of temperature is entirely borne out by closer investigation. As a rule, the temperature in these cases is not taken, as the patient is about, is not conscious of any fever—the skin appears cool, there are no objective symptoms of febrile temperature. But systematic thermometric measurements have shown that even in these mild cases, in common lumbago or stiff neck, slight elevations of temperature, 100°, 100.5°, 101° F., are much more frequent than is commonly supposed. A further point that deserves mention is the question of endocarditis in muscular rheumatism. The occurrence of endocarditis in the train of muscular rheumatism is altogether denied by many observers. Now, it is beyond doubt that endocarditis, while of frequent and almost regular occurrence in acute articular rheumatism, is but rarely observed in muscular rheumatism. But it certainly does occur. In this respect, too, the facts bear out entirely Leube's statement. Endocarditis is met with not only in those severe cases associated with considerable elevation of temperature as mentioned above, but also now and then in quite mild cases of lumbago, stiff neck, etc. Endocarditis is occasionally found in children apparently without history of rheumatism. Closer investigation elicits a story of transitory pains (growing pains) here and there in the legs, the arms, over the back. The joints are absolutely normal, but careful palpation detects recent and painful infiltration in one or more muscles. In the case of adults, too, it is by no means rare to find a valvular lesion without any satisfactory etiology to account for it. There is no history of articular rheumatism, pneumonia, typhoid, syphilis, or other infectious diseases. Careful palpation, however, demonstrates in various muscles sometimes quite numerous more or less hard patches of infiltration as the residue of former attacks of muscular rheumatism, which, while not severe enough to have dwelt in the memory of the patient, sufficiently account for the endocarditis and resultant valvular defect. One other point deserves mention: It is customary to look upon lumbago, stiff neck, and other similar very sudden myalgias as caused by traumatism, as due to muscular strain or distortion. It is indeed certain that in very many of these cases, though by no means in all, the acute attack of pain appears to be brought about by some sudden and abrupt motion (stooping, lifting, rapid turning of the head, etc.). Leube, who is of the opinion, as I am, that even these cases of so-called myalgia must be considered as genuine rheumatic infections, admits that this apparent connection of traumatic injury with the outbreak of an acute attack of rheumatic affection is at present entirely unexplained. From the point of view advocated in these pages the symptom is, however, not difficult of solution. In all of these cases interstitial myositis with more or less infiltration, which, as has been shown above, may lie dormant without objective symptoms for an indefinite time, is present and may have existed for a long time. The myositis is in every case the primary affection. Under these conditions a sudden violent and abrupt motion simply lights up a renewed and acute attack of inflammation and pain, possibly by causing a slight intra-muscular hemorrhage, or by rupture of bundles of already well-degenerated muscle fibres or of infiltrated and degenerate nerve branches, etc. All this is not mere speculation, but can easily be proven. There are numerous persons who suffer, sometimes for many years, from recurrent attacks of this form of rheumatism, for instance from lumbago. In every one of these cases it is possible in the interval between the attacks, and at times when there are absolutely no subjective symptoms, to demonstrate muscular infiltration in the quadratus, longissimus dorsi, or other muscles of the trunk, and it can be shown that in every attack the pain unfailingly takes its origin from those spots which have been recognized as the seat of the infiltration. Let it be stated plainly once more, however, that numerous instances are observed in which the attack comes about without any traumatic influence whatsoever.

Rheumatic myositis can occur practically in almost every part of the body where there are striated muscles. But very few localities have thus far been found exempt. It may perhaps be of some interest to dwell on some of the rarer and less generally appreciated localizations. The muscles of the head are more often the seat of rheumatic inflammation than is commonly supposed. The disease occurs not only in the muscles of mastication, the temporal, and, though quite rarely, in the masseter, but also and very frequently indeed, in the occipital and the small muscles at the base of the occiput. In these latter localizations it is common to find the cutis, especially the galea, and the nerves equally involved, and the pain caused by these foci of rheumatic inflammation is usually diagnosed as an ordinary cephalalgia or headache, or as neuralgia. Palpation readily detects patches in the muscles, the skin, and also about the nerves. The occipital nerve, just at its exit, is a favorite locality. Many cases of headache, occipital, supraorbital, and other neuralgia, many cases of so-called migraine, are nothing else than rheumatic inflammations easily to be recognized by proper examination. There are, however, other localizations which occasionally may render the proper interpretation and diagnosis rather difficult. I wish to speak particularly of those cases of rheumatic myositis localized in and about the abdominal muscles, which are not generally recognized and may be of considerable clinical importance, inasmuch as they may simulate cholecystitis, appendicitis, and other affections of the abdominal viscera. With reference to cholecystitis the following case may serve as an illustration:

Mrs. H. I——, forty-five years old, was very suddenly seized with excruciating pain. The pain was distinctly localized in the region of the gall bladder and radiated from there into the back and epigastrium. The entire region was extremely sensitive to the slightest touch, and even the ordinary respiratory movements caused pain. The rectal temperature ranged from 100° to 101° F.; the pulse was normal. All the other organs were normal. The suddenness of the attack, the strict localization in the region of the gall bladder, the fever, suggested a possible acute cholecystitis, perhaps with incipient peritonitis. On the other hand, it could be urged that the woman had never before suffered from biliary colic, while she had at various times been subject to rheumatic affection. The very slight pyrexia as compared with the extent and acuteness of the pain seemed to tell against the assumption of a severe and deep-seated lesion. Further observation seemed necessary before a positive diagnosis could be made, though rheumatism was thought most probable. After a few full doses of salicylate of sodium the sensitiveness of the area affected had diminished to such a degree that a thorough palpatory examination could be made, which demonstrated fresh inflammatory infiltrations in the muscles just below their insertion at the right border of the ribs. A few months later the same patient was seized with an entirely similar attack, the difference being merely that the inflamed area of muscle was located in the right quadratus lumborum.

Localization of myositic patches in the recti abdominis is rather frequent and may lead occasionally to errors in diagnosis if not carefully considered. This is particularly true, too, of rheumatic myositis in the obliqui, and especially when located in the internal obliquus in the region of the right iliac fossa. It is at times extremely difficult to distinguish between an incipient appendicitis and a rheumatic affection of the deep muscles and fasciæ. The occurrence of this class of cases is by no means generally appreciated, and indeed the very possibility of rheumatic myositis in the abdominal muscles is not taken into account by the majority of practitioners. It may be well, therefore, to say a few more words on this subject, the more so as the impression seems justified that in the present state of nervousness concerning appendicitis which obtains among the profession as well as among the laity, not a few cases have been diagnosticated as appendicitis, and not a few perfectly normal appendices have been removed, when the actual lesion was merely abdominal rheumatic myositis. The following observation well illustrates some of the points in question:

Mr. S. J——, forty-seven years old, complains of general malaise, loss of appetite, and pain, which latter, gradually growing more severe, is located by the patient in the right side of the abdomen. The family physician finds rise of temperature, ranging from 100° to 101.5° F., and a diffused sensitiveness on pressure all over the right abdomen. No positive diagnosis is made. Ice bag to the painful parts, mild saline laxatives, and rest in bed, together with strict diet, are ordered. In a few days the pain moderates, the temperature is almost normal, and the general condition much improved. The patient is then advised to take a week's rest out of town. While away from the city he feels comparatively well; appetite improves, vigor returns, but he is never quite free from pain. On his return I find a slow, regular pulse, somewhat coated tongue, the viscera of the chest perfectly normal. There is a distinct and intense painfulness on pressure over the region of the appendix. The appendix itself cannot be distinctly made out. There is also a slight sensitiveness just below the right arch of the ribs about the region of the gall bladder. The liver is not enlarged. Jarring and percussion of the liver are not painful. Pressure over the region of the appendix causes the pain to radiate upward toward the epigastrium and gall bladder, and is so painful as to predominate over all other sensations. The rectal temperature is 100° F. No albumin, no sugar, no phosphates, and no biliary elements are found in the urine. A second examination next day after the bowels have been thoroughly evacuated led to exactly the same result. The conclusion seemed obvious that the case was one of mild subacute appendicitis. With a view to a possible operation a surgeon was consulted, who in turn was disinclined to entertain the diagnosis of appendicitis, but rather favored cholecystitis. Further observation of the patient showed the sensitive areas remaining about the same, with this difference: On one day the pain about the region of the gall bladder would be more severe, and the next the pain about the region of the appendix. In the mean while I had recollected that the same patient had at various times suffered from rheumatic myositis in the muscles of the neck, leg, back, etc. The somewhat uncertain and undetermined symptoms in the present trouble suggested the possibility of a rheumatic condition. Accordingly a careful palpation of the muscles was made, and the infiltrations in the obliquus externus and in the rectus, the latter under the arch of the ribs, were readily discovered. An energetic antirheumatic treatment rid him promptly and entirely of all pain and discomfort. If the possibility of rheumatic myositis had suggested itself to me, as it should have done at the first, and the proper examination of the muscles had been made at once, the patient as well as his physicians would have been spared much worry and anxiety. Some time afterward the same gentleman was seen with a new pain, but this time located distinctly in the right quadratus.

In the following case the condition was less perplexing:

Mrs. E. S——, twenty-nine years old, had for some time been suffering pain in the right iliac fossa. She was seen by a prominent gynæcologist, who found the uterus and adnexa normal, but diagnosticated incipient appendicitis, and sent her to bed, and ordered ice-bag and expectant treatment. Temperature, pulse, and digestion were normal, and the appetite was good. Pain on motion and on pressure was quite violent and strictly localized in the right iliac fossa about the region of the appendix. This patient, too, had at various times suffered from muscular rheumatism in various parts. Palpation showed a firm infiltration in both obliqui, and salicylate of sodium and massage effected a speedy cure.

Accounts of similar cases might be multiplied almost indefinitely. Examples might be adduced in which myositis of the recti simulated peritonitis or intestinal colic, when myositis of the quadratus and obliqui was diagnosticated as renal colic, but perhaps this will suffice to show that rheumatic myositis of the abdominal muscles must be taken into consideration as among the possibilities in all cases of painful abdominal affections in which the diagnosis is at all doubtful. It would transgress the limits of this paper to enter into details upon the numerous questions of differential diagnosis in this group of cases. It may be stated in a general way that the absence of progressiveness of the symptoms, the tendency to remain stationary, characterize most of these rheumatic affections. Moreover an attack of rheumatic myositis of the abdominal muscles is rarely the first rheumatic attack. Usually there are a history and physical evidence of preceding or simultaneous rheumatic affection in other parts of the body. The absence of fever or the very slight elevation of temperature, the absence of characteristic symptoms on the part of the abdominal viscera, are in many instances valuable hints. The main basis of the diagnosis, however, is in every case the demonstration of the muscular infiltration or indurations by palpation. This is at time extremely difficult. In very fat individuals or in hyperæsthetic and hysterical subjects it may be practically impossible. In every case a delicate and well-trained sense of touch is required. The recti and quadratus are, as a rule, more easily handled. When the patient is in the recumbent position or on either side with flexed thighs, it is not too difficult to grasp the rectus between the thumb and first two fingers, or between the two hands, and palpate all through the muscle. The obliqui, particularly the obliquus internus, present the greatest difficulty. Palpation here can never be properly carried out while the patient is on his back. It is necessary to turn him well over on either side and with muscles thoroughly relaxed. In every case palpation of the obliqui requires great practice and a delicate touch.

It has already been stated above that, no matter whether the acute initial symptoms are of considerable intensity or so very mild as to be barely noticed, muscle infiltrations remain in every case. These enduring infiltrations and indurations in the interstitial muscular tissue, the neurilemma, and the subcutaneous and adipose tissue form the basis of chronic muscular rheumatism. It is owing to these infiltrations that more or less severe relapses take place at all times and on the slightest provocation. But not only periodical relapses are caused by these anatomical lesions. Permanent disturbances of motor function, such as pain with certain motions, contractions of certain muscles or groups of muscles, are frequent occurrences. If the muscles involved are numerous and the indurations extensive and hard, really intolerable conditions, seriously affecting the working-capacity and the entire functional economy, may result. Besides this effect on motor function, other disturbances can be brought about by these indurative processes which have as yet received too little attention at the hands of the practitioner. I refer particularly to periodical attacks of pain simulating typical neuralgia. There are, for instance, certain forms of headache resembling altogether typical migraine which are entirely due to rheumatic lesions.

Soon after I had first begun to study the various forms of rheumatic myositis, a gentleman, Mr. S——, presented himself at my office complaining of periodical seizures of very violent hemicrania with all the symptoms of ordinary migraine. The attacks occurred at varying, entirely undetermined intervals, even as often as several times in one week. The suffering caused by the violent pain was not always mitigated even by large doses of antipyrin or phenacetin, and, moreover, was the cause of serious disturbance in the carrying on of his business. He had accordingly consulted numerous nerve and other specialists without relief. He stated that he had never been seriously ill, but had had frequent mild attacks of rheumatic pain in his limbs and suffered very often from lumbago. All internal organs were found on examination perfectly normal. In the small cervical muscles, however, in the cucullaris, temporalis, and in the scalp numerous rather hard infiltrations were found, as also about the trunk of the occipital nerve, which latter was particularly hard and painful. A very energetic and systematic course of massage extending over several months gave permanent relief from all unpleasant symptoms, and the patient has since then had no recurrence of his periodical attacks of migraine.

Since that time many similar cases with similar results have been observed. The following case may also be of interest:

A young widow, Mrs. P——, about twenty-seven years old, suffered for years from violent attacks of headache which lasted for days at a time, confining her to her room and practically keeping her from all social duties and pleasure. The father of the lady, it is stated, had been subject for years to similar attacks, and finally died, according to the reports of the autopsy, from hemorrhagic pachymeningitis. The young lady, convinced that before long her father's fate would overtake her, had fallen into a condition of hopelessness bordering on melancholia. Careful examination showed all internal organs, including the brain and spinal cord, to be perfectly normal. Examination of the eyes was also negative. She positively denied ever having suffered from rheumatism or rheumatic pain anywhere; notwithstanding this most positive statement numerous infiltrations were found, as in the previous case, in the muscles of the neck and head and about some of the nerve trunks. In this case also proper massage permanently relieved the headache and restored the patient to a rational enjoyment of life.

Similar conditions can prevail in other regions of the body, particularly in the extremities. There are cases which present all the symptoms of chronic sciatica. Indurations are found in the gluteal muscles or in the neighborhood of the sciatic notch, and the removal of these by massage or excision (Straus) at once relieves all sciatic symptoms. Numerous other instances might be cited and corroborated and illustrated by clinical histories. It will be proper, however, to let these few hints suffice, and proceed to a brief consideration of the etiology of muscular rheumatism.

It is the almost universal opinion at present, as is manifest also in the above-quoted statement from Lorenz, that exposure to cold is the most frequent, in fact the sole, cause of muscular rheumatism. A discussion of the rôle of "cold" as an etiological factor in disease would lead me too far. But it may be stated in a general way that a survey of the history of medical science demonstrates clearly the indubitable fact that with every advance toward a more intimate knowledge of disease, cold as an etiological factor is less frequently heard of. Compared to twenty-five years ago but very few diseases are to-day considered as in any way attributable to cold, and it is significant that these are such as to whose etiology but little is definitely known. Muscular rheumatism is the last stronghold, as it were, of this once so universally dominant etiological concept. But here, too, it has outlived its usefulness. Sahli has shown that articular rheumatism is most probably caused by infection with cocci, staphylococci, or streptococci of attenuated virulence. We have seen how closely related muscular rheumatism is to articular rheumatism. They are not only frequently associated, but the facts that in pure muscular rheumatism fever is often present, endocarditis is not infrequently observed, and erythematous eruptions, peliosis, are not rare, seem to suggest the inference that muscular rheumatism must also be classified among the infectious diseases. The old and well-established observation of the migratory tendency of rheumatism, its appearance in different regions of the body simultaneously, or now here, now there, in rapid succession, points in the same direction and is best explained by the infection theory. I conclude, therefore, in accordance with Leube, that rheumatic myositis is an infection, caused most probably, according to present lights, by cocci (streptococci), still less virulent than in rheumatic arthritis. Assuming this to be so, we have gained a uniform basis for the entire group of infectious muscular diseases. First in order and of least virulence would stand the rheumatic interstitial myositis; next and more virulent those graver forms of myositis associated with a severe type of articular rheumatism. Of greater virulence still are the true septic types of myositis, those forms which result in extensive interstitial proliferations and formation of pus, which lead to muscle abscesses. We must further classify under this general heading those more specific forms of interstitial myositis which occur so frequently in the course of infectious fevers, especially in typhoid. These are, however, no longer pure types of interstitial inflammation, inasmuch as, probably caused by specific toxins, a primary degeneration of the muscle fibre takes place, as a rule, simultaneously with the interstitial process. Syphilitic interstitial myositis may possibly also belong to this group, though to me this seems doubtful. It must be candidly and unreservedly confessed that this entire conception as just stated has as yet not been strictly proven, and is still more or less hypothetical in character. The cocci have not yet been demonstrated, and even if we assume their existence we are in utter ignorance of their mode of entrance into the system, the conditions which influence their invasion, etc. Nevertheless it can safely be said that this view has the advantage of gathering a large group of pathological processes under one uniform conception, and of affording a more logical and plausible explanation of observed facts than the entirely inadequate theories that are based on hypothetical effects of cold, damp, etc. But even if we assume the above-stated views to be correct, it cannot be denied that there remains much that is as yet unexplained. Though we cannot admit that colds or exposure can cause an interstitial myositis, no one can doubt the truth of the empirical observation, as old as the history of medicine, that climatic conditions exercise to a certain degree a disposing influence upon rheumatic affections. Just in what way we are to explain this remains for the present an unsolved problem. Again, it seems certain that diet and general mode of living may furnish a disposition toward rheumatic muscular affections. This fact may perhaps be not entirely inexplicable. Observation has shown that vigorous muscular activity affords considerable protection against rheumatic infection, while indolent and sedentary habits favor a direct disposition toward this class of disease. The same can be said of excessive and rich feeding and of even moderate abuse of alcohol. Considering the extremely abundant blood supply of muscles, their intense and variable metabolism, and their ability to store up certain chemical substances, such as glycogen, lactic acid, etc., it becomes quite conceivable how, under the above-mentioned conditions, a favorable or unfavorable breeding-ground for infective germs may result.

In conclusion, some few words must be said about treatment. The acute cases with fever and severe pain are treated as any ordinary case of articular rheumatism. The patients are kept in bed and salicylates are administered. In a general way I am under the impression that salol and its compounds act more satisfactorily in muscular rheumatism than salicylate of sodium. In most cases, too, I see better results from the local application of cold (ice-bag) than from the hot fomentations and hot-water bags which are so generally favored. The old notion, still widely accepted, that acute rheumatism, whether muscular or articular, must be treated by hot applications, and that all cold must be carefully avoided, should at last be given up. We have seen that every attack of muscular rheumatism is essentially a proliferating interstitial myositis with more or less inflammatory infiltration of the muscles. After the subsidence of the acute stage these infiltrations remain, undergo further changes, and lead to recurrence of further acute attacks, to disturbances of function, and to many other painful and otherwise annoying symptoms. It should be the main object of our therapeutics to accomplish the removal of these infiltrated patches and reinstate normal anatomical conditions in the muscle. We have essentially local lesions which can be satisfactorily dealt with only by local measures. The well-known hot baths and springs, electricity, the internal administration of iodides, gymnastics, and the host of other remedial schemes that have been recommended, will produce no lasting result. Though I will not deny that they may be useful with regard to the general conditions, with reference to circulation, excretion by skin and kidneys, improving metabolism as a whole, etc., it is safe to say that they will scarcely touch the local lesion which is our main objective. The rheumatic infiltrations and indurations can be best dealt with by proper massage. Not every so-called masseur understands this, and I am far from indorsing the loose and unscientific handling that has of late years become rather too general under the collective name of massage. For our purpose the masseur must be possessed of a specially trained tactile sense in order to find even the slightest infiltrations, and a special technique is required in their treatment. Quite soft and recent infiltrations are handled differently from old and hard fibrous indurations. In the latter the object of the massage is the forcible breaking up of the fibrous masses and the production of reactive hyperæmia and inflammation which will gradually under persistent and judicious treatment end in absorption of the fibrous induration and in new formation of muscular tissue. In the former the procedure is simpler and easier, though the principle is the same. This is not the place to enter into further details. Very few masseurs understand, and are trained for, this special work. The well-known Dr. Metzger and his pupils have earned their laurels principally in this field. In our city Dr. Norström has devoted himself specially and successfully to this work. We know from careful and convincing microscopical investigation that, as the inflammatory products are absorbed, and under the influence of strongly stimulated blood supply, the muscle fibres are rapidly regenerated and take the place previously occupied by the inflammatory proliferation. It is astonishing to see indurations almost cartilaginous in their hardness still yield to persistent and properly applied massage. It is evident, however, that recent still well vascularized and cellular infiltrations will be absorbed much more quickly and easily than old, hard, and dense indurations. For this reason it is well to commence the mechanical treatment as soon as the acute stage of fever and intense spontaneous pain has passed. We will then be able very often to obtain complete absorption and restitution in a very short time. In every case the treatment requires some pluck and energy as well as persistence on the part of the patient, for it is obvious that this kind of massage is necessarily quite painful, especially at the beginning of the treatment. As the infiltrations are reduced the painfulness of the massage rapidly diminishes. The rare cases of genuine muscular cicatrization (*Muskelschwiele*) can, it is obvious, derive no benefit from massage. In these cases the fibrous cicatricial tissue must be excised. This has repeatedly been done with excellent result. Recently such cases have been again reported by Strauss.

Finally, reviewing once more the entire subject, I may briefly summarize the conclusions arrived at as follows:

The so-called muscular rheumatism is, according to probability and analogy, an infection with germs, most probably streptococci, possibly staphylococci, of attenuated virulence.

A certain degree of individual disposition toward this class of affection is recognizable. This disposition is augmented by indolent and sedentary habits, by improper nutrition, especially immoderate and rich eating, and alcoholic beverages. It appears, furthermore, that climatic influences may also, in a manner as yet unexplained, act favorably on the development of rheumatic affections.

Muscular rheumatism must be designated anatomically as an interstitial myositis, usually in conjunction with inflammatory processes in the adjacent tissues, the subcutaneous and fatty tissue, the fasciæ, and especially the nerves. In the latter the process is likewise that of interstitial neuritis.

As sequelæ of the inflammatory process, cellular infiltration, connective-tissue indurations, and sometimes even complete fibrosis of the muscles are produced. These changes in the muscular texture persist after the abatement of the acute inflammatory conditions and give rise to more or less frequent relapses and to manifold functional disturbances.

Mere medicinal treatment is indicated in the acute, more or less febrile stage. As soon as this stage is over, mechanical treatment, especially proper and adequate massage, becomes of paramount importance. It is the object of this method to bring about the absorption of the infiltrations and indurations and to restore the muscle to normal conditions.

Postscript.—Since the above paper was written, Wassermann has succeeded in isolating a streptococcus from the blood and various viscera in the case of a girl who died from endocarditis, nephritis, and chorea following polyarticular rheumatism. Injection of small doses of the pure culture of this streptococcus into the blood of rabbits invariably produces typical, usually fatal polyarthritis in the animal. The infectious nature of rheumatic polyarthritis, as caused by a specific streptococcus, can therefore be considered as certain. It will remain an object of investigation for the near future to determine if similar micro-organisms cannot be found for muscular rheumatism.[1]

OBSERVATIONS ON THE TREATMENT OF CANCER.[2]

By A. R. ROBINSON, M.B., L.R.C.P. and S. Edin.,

PROFESSOR OF DERMATOLOGY IN NEW YORK POLYCLINIC; ATTENDING PHYSICIAN TO THE MEMORIAL HOSPITAL (CANCER HOSPITAL), ETC.

A few years ago I read a paper before the Toronto Medical Society on the treatment of cutaneous malignant epitheliomata, and after a full consideration of the different forms of cutaneous cancers, and especially of their pathological anatomy and methods of extension, endeavored to show both from a theoretical and clinical standpoint that, in a majority of cases coming under the observation of the surgeon, certain caustics applied according to the principles laid down by me, principles based on the nature of the action of the caustic employed, the form of the epithelioma present, and the extent and direction of the invasion of the normal tissues, gave much more satisfactory results as regards the complete removal of the disease and the amount of deformity from the operation than could be obtained by the use of the knife; that in a certain number of cases the knife was the proper agent to employ; that in a few cases the knife, followed immediately afterward by a caustic, should be used; and, finally, that some cases were best treated by the curette, followed by a caustic.

This view I will to-day again maintain and defend, as I firmly believe it to be in the interests of those afflicted with this dreaded disease.

Three years ago I read a paper before this association on the importance of early treatment in all cases of cancer, an importance well known to the profession in theory long before I was born, but, I am sorry to state, strangely neglected in practice even to this day, if I may be permitted to judge from the knowledge which a rather large personal experience in the matter gives me. To this lamentable neglect allow me to attribute a considerable percentage of the cases of death from cancer, for it must be admitted that many cases of the malady which have proved fatal could have been treated successfully, provided the proper method had been followed at a sufficiently early stage. In that paper I endeavored to show from a pathologico-anatomical and etiological standpoint that treatment other than such as would promptly and radically remove or destroy all of the pathological tissue, generally only injured the patient and favored a more rapid extension of the disease.

---

[2] Paper read at the annual meeting of the Canadian Medical Association, held in Toronto, August 30, 31, and September 1, 1899.

Having thus gone over the subject on previous occasions, it was my intention, when I first concluded to write a paper for this meeting, to devote the whole article to a report of the observations and experiments made by me during the last twenty years with different drugs which had been previously lauded by others in the medical journals, or used by myself independently in the search for a something that can control or stop the growth of cancer wherever situated; also to report observations made on local treatment with different agents and methods of application, especially as regards caustics in those cases that have shown the mistakes I had made in the manner of using them, being followed by unfavorable results—results that, experience has taught me, would probably have been avoided had there been no fault in the method of treatment. Owing, however, to the statements contained in a recent article on the subject of cancer by one of the leading surgeons of England, I shall hasten over the report of these personal observations and studies, as I wish to join issue with some of the statements contained in the aforesaid article, believing it to be to the interest of medical science in general and for the benefit of cancer patients in particular.

As regards the effects of treatment by internal medication upon the life of a cancer, as far as my experience goes, I know of no drug or preparation, serum or toxin, single or combined, that is entitled to be regarded as a specific for cancer, or that gives hope of being of special benefit in any form of cancer at any stage of the disease. The use of any substance that makes a profound and disturbing impression upon the nutritive processes of the body usually has an inhibitory action on the growth of cancer, and temporarily there may be, as a consequence, a cessation in the growth of the tumor, or even a marked diminution in its size. For example, there is a case on record of the disappearance of a mammary cancer after an attack of typhoid fever. I have seen cases of superficial epithelioma disappear when the part was the seat of an ordinary infective dermatitis by pus organisms, and have also known of some which disappeared spontaneously after lasting years, the ground condition evidently having been unfavorable for a continuance of the morbid process. Such a result as that noted after typhoid fever should encourage studies in the direction of seeking an agent which would be selective in its destruction, and which would enable us to give a ray of hope to those cases now regarded as inoperable no matter in what stage they are observed. Personally I have no faith in the result of efforts made on the lines so successful in such diseases as diphtheria, diseases of limited duration; the result of immunity acquired by the tissues. Cancer is not a self-limited disease, and I cannot understand how one could expect to obtain an anti-cancerous serum in the same manner as anti-diphtheria toxin is produced, and count upon its having any influence on the disease. I might state that, as far as my studies and experiments go, I am no believer in a microbic origin of cancer.

I shall not enumerate all the drugs I have tried, nor give the reasons for using them, but for the present occasion I shall state that mercury, iodide of potassium, sulphur, sulphide of lime, turpentine, some essential oils, arsenic, chelidonium, nuclein, ovarin, thyroid extract, and suprarenal extract have been tried faithfully, and all have failed to stop the course of the disease. A few remarks on the observations made with some of these substances may be interesting. Although iodide of potassium has been of marked benefit in some of the few cases of blastomycetic dermatitis which have been observed, I have never yet in cancer seen the slightest beneficial action from its use, whether the drug was given in large or in small doses. This is, *a priori*, a point of some value and not to be forgotten by those who claim a blastomycetic origin for cancer before having the necessary scientific proof for this view.

Dr. Sherwell, of Brooklyn, from large clinical experience believes arsenic has such a decided beneficial action in cancer that it is wrong not to give it in every case under treatment, but I have never yet been able to satisfy myself that it has any special favorable action, even in the most superficial forms of cutaneous epithelioma, and my experience agrees with that of almost all observers.

The first case treated by nuclein was one of inoperable uterine cancer in an advanced stage, and the temporary change in the patient's condition was so satisfactory that had I not very soon placed several other patients under the same treatment, I might have formed a wrong opinion as to its possible value in this disease. This was at least six months before any literature had appeared reporting wonderful benefit from both nuclein and proto-nuclein. This first patient, after having been in bed several weeks and in consequence of pain and general weakness having been kept under the influence of morphine, was given nuclein, and in less than a month was able to leave her bed and do slight household duties. Gradually her general health and also the local symptoms improved, and for nearly two years she was in a comparatively comfortable condition, doing her own shopping as well as some housework. Then the disease took on new activity, commenced to extend rapidly, and death soon followed. During the last three or four months of her life I had tried other drugs. Further experience convinced me that neither in internal nor in cutaneous cancers is the drug of any special value.

The natural history of cases of internal cancer especially is so variable that one is not justified in forming even an opinion from a single instance.

I treated several cases of cutaneous cancer (inoperable, of course) with a dried extract of the skin of the pig prepared for me, but did not notice any effect on the disease. I have found the avoidance as much as possible of meat diet, and the drinking of large quantities of water, to have had decided beneficial effects in many cases of carcinoma. I have seen a mammary cancer diminish very much in size under a vegetable diet and the drinking of four quarts or more of water each day.

Thyroid extract, suprarenal extract, and ovarin have not benefited any of my cases, either uterine, mammary, or cutaneous, and yet I am inclined to believe that some gland extract will be the agent of the future for cancer, just as thyroid extract is to-day for certain diseases.

I repeat that I am not aware of any substance, whether drug, serum, or toxin, which, given internally, by the mouth or otherwise, can be regarded as a cure for internal or external cancers at any stage of the disease, and the moral I would draw from these observations is, that a physician is not justified in losing valuable time in operable cases by prescribing drugs, either in the hope of a possible value or because the patient hesitates to undergo proper treatment.

Local Treatment of Cutaneous Cancers.—In the interests of the regular medical profession and of the subject of cutaneous cancer, I feel it my duty once more to discuss the subject of local treatment, and to give the reasons why, in my opinion, the majority of cases of cutaneous cancer—and cutaneous cancers form the majority of all cases of the disease—should be treated by caustics, or very similarly acting agents, instead of by the use of the knife.

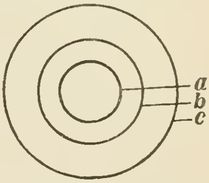
Let us consider the argument of those who think the knife should be used in all cases of the disease admitting of operation. A full discussion of the origin and method of growth of cancer would aid in making clear the grounds upon which I regard a caustic as usually preferable to the knife, but because my time is limited I shall be able to touch upon this only in a very general way. Let me here in passing remark that I believe a knowledge based on microscopical studies of the normal skin and of the pathological process in cancer is necessary for an intelligent handling of a case of cutaneous epithelioma.

In a late number of the *Practitioner*, a so-called "cancer number," there is an article on the treatment of cancer by Mr. Watson Cheyne, in which he states that all attempts to cure the disease by other means than operation by the knife "are almost invariably futile, for the reason that caustics and injections do not attack the outlying deposits." This view, in so far as it relates to certain caustics used by experts in the treatment of epithelioma, I regard as quite erroneous and not in accordance with the clinical experience of those who have had ample opportunities for study and observation of the results by the different methods of treatment; furthermore, I do not think it is to the interest of those afflicted with cutaneous cancer to allow this statement by such a distinguished and worthy surgeon to remain unchallenged. It may be labor in vain to ask the knife surgeon to consider carefully the other side of the question; to ask him to treat forty or fifty suitable cases of epithelioma in the manner they should be treated when caustics are used, and to compare notes with similar cases treated by the knife; but if he does make such a study he will find that outlying deposits—not distant infected lymph glands—can generally be attacked directly or indirectly with much more certainty, and with decidedly less deformity as a result, by proper caustics scientifically applied, than by the most skilful use of the knife.[1]

If Mr. Cheyne referred only to internal cancers, or to nearly every case of mammary cancer, or to cancers of any kind or location in which the lymphatic glands are already affected, then his statement would be about correct; but it is not correct for primary cutaneous cancer, except when it is located on certain parts of the body, to be mentioned directly.

Allow me to describe what can be accomplished by the use of a caustic, employed in the manner and on the principles already laid down by me in previous articles, and then judge for yourself as to the value of the statement made by Mr. Cheyne.

I have here a diagram in which I have represented a cancer as occupying, according to the naked-eye appearances, the area within the circle *a*. We all know, however, both from clinical experience and microscopical examination, that this area is not in reality the limit of the disease in any single case, but that there is always pathological epithelium beyond this line, and I have assumed that it invariably extends as far as the circle *b*; the infiltration being greater the nearer *b* is approached. We will also assume that some epithelia are often outside the area enclosed by *b*, but not outside the circle *c*. Let us further assume that we have to deal with the usual form of a cutaneous epithelioma of the face, a tumor usually of slow growth, with a tendency to extension in a horizontal direction in the skin more than in a downward one, and with very slight tendency to lymph-gland infection, especially in its early period of existence. My argument, however, will hold good for all the forms of cutaneous epithelioma, and this one form is chosen merely in order not to occupy too much of your valuable time, and also because it should be sufficient to enable you to form a judgment on the soundness of the argument I wish to make. If the surgeon operates with the knife in such a case, he makes the incision a considerable distance outside of the apparent margin at *a*, knowing that in reality the disease always extends beyond that margin. Suppose he make the incision at *b*; say, half an inch or more outside the apparent limit at *a*, and is careful also to cut deeply enough and has by such an operation removed all the pathological epithelium; the operation will be a success as far as the removal of the disease is concerned, and the only question remaining as regards the justice of the operation will be the consideration of the amount of mutilation necessarily resulting from the operation as compared with the resulting deformity after any other method giving complete removal of the disease; and when the cancer is situated upon the face the question is of much importance, for of two operations giving similar results as regards cure, the one causing least deformity should always be chosen if at the same time the danger from the operation is not greater. This point will receive attention from me later on in the address.



If pathological epithelia are present in the area between *b* and *c*, and from clinical observation we know that unfortunately they often do exist, let us say, more than half an inch beyond the apparent limit, as shown by the frequent so-called recurrences (really naked-eye reappearances and not recurrences, as the removal in these cases had not been complete even if the surgeon feels satisfied he has removed sufficient tissue), and the incision is made at *b*, the wound being kept in an aseptic condition, and healing by first intention, then being uninjured, those outlying epithelia will continue to proliferate, and in time will become visible to the naked eye or recognizable through the sense of touch. In other words, the disease has reappeared, and the operation was not a successful and radical one. Such a result will occur every time that an incision is made at *b*, and there is healing by first intention, if any pathological epithelia are outside the line of incision. In this case the knife has not attacked all of the outlying epithelia, and the aseptic method of treatment of the wound has left these epithelial cells uninjured and still possessed of all their inherent powers of proliferation. In my opinion such a wound should immediately after the operation be soaked with a solution that would penetrate for some distance into the open lymph channels and injure the epithelia within them, or destroy the microbe if the disease is a parasitic one. I have during the last few years used various agents with that object in view, and am still working on in that line, as I have been encouraged by apparently good results. It is a point I think worthy of consideration, study, and experiment, especially in connection with the treatment of cancers such as those of the mammary gland and rectum, and also in cutaneous cancers in which there is invasion of the lymphatic glands. It is not necessary that the solution employed should interfere with the healing-process.

If the incision with the knife were to be made at *c* and carried sufficiently deep, the disease would certainly be completely removed, as there would be no pathological epithelia left, and in this case we would have merely to consider the extent of the mutilation from the operation as compared with other methods giving as complete a removal of the disease.

---

[1] I desire to state that some surgeons in New York City have been convinced of the value of caustics. At present I have three cases under treatment referred to me by a teacher of surgery in that city, and I know of other teachers here who do not in each and every case use the knife.

You will observe that I am discussing the treatment of a cancer of moderate size, capable of removal by the knife and also by caustics. Other forms of epithelioma as regards location and extent will be briefly referred to later on.

Now as to the action of a caustic in such a case as I have chosen for illustration; for the sake of brevity I shall limit the description to that of the action of arsenious acid, as that is the caustic agent most frequently employed in the treatment of cutaneous cancers. Probably the majority of those who use this agent in cancer believe that it possesses above all other caustics in this disease a special selective injurious action on the pathological tissue, a special antagonism to the epithelial structures comprising the new growth, or possibly the organisms if it be a parasitic disease. Hence it is preferred to the other caustics in nearly all cases in which it can be used with safety, that is, without danger of poisoning the patient. A paste made by adding sufficient water to equal parts by weight of arsenious acid and powdered gum acacia to give it the consistency of butter, and applied over the whole area as far as *c*, will cause, as a rule, within a period of from sixteen to eighteen hours a complete necrosis of all the tissue within *a*, provided the part is in such a condition as to allow the paste to act upon the pathological tissue, and this condition exists when a raw surface is present and the cancer does not lie beneath fairly normal epidermis. I state that usually such will be the action of the paste in that length of time, but naturally the extent of the action will vary in any given case according to the vulnerability of the part to which the caustic is applied, as well as to the duration of the application. A stronger paste, such as one made of two parts of arsenious acid and one part of gum acacia, would cause the same amount of necrosis in a less period of time, perhaps in from eight to ten hours. The operator must know the amount of destruction required in a given case and how much has occurred; that is, whether the desired action has been obtained from the application—otherwise the results will be unsatisfactory. Only experience will teach the proper handling of the cases. Sometimes the area *a* is completely necrosed in twelve hours, and in other cases not in twenty hours, but this amount of necrosis can and should be produced by the paste.

Permit me to emphasize the fact that the part to which the paste is to be applied must be in a condition to allow of the action of the caustic; for instance, if the epithelioma has started from a hair follicle and is still a deep-seated epithelioma, the epidermis over it is for a time in a fairly normal condition, and in this case the surface epithelium must be destroyed by means to be described later, in order to allow the paste to attack the pathological tissue, as normal tissue resists the action of arsenious acid very much longer than the cancer tissue. As I have stated, the result to be obtained, and which can always be obtained, is complete necrosis of all the tissues within *a*. With such action there is invariably an acute inflammatory process extending much beyond *c*, and increasing in intensity the nearer it is to *a*, since the tissue increases in vulnerability as the latter circle is approached. When you have obtained such a marked action from the caustic, you have secured what is demanded for the proper treatment of the case. A longer application would destroy more tissue than is essential and cause unnecessary deformity, while less destruction would probably not kill all the cancer deposits outside of *b*. That such action as I now describe as necessary can be obtained by arsenious acid needs no discussion here, and the statement that a caustic cannot directly or indirectly attack "outlying deposits," such as are usually present in cutaneous cancer, is not based on fact. The truth is that many times, especially with dispensary patients, I have destroyed much more tissue than was necessary, owing to the impossibility of having the patients under observation during the whole period of application of the paste, so as to be able to judge when the proper amount of action had been obtained.

Let us consider the effect of such an action as I have described as proper and necessary upon a cancer which has been treated by the caustic, and compare it with the result obtained when the knife was used.

All of the tissue within *a* has been destroyed, deprived of its vitality, and also some of the tissue beyond *a* on account of the very intense inflammatory process there, the tissue being much more vulnerable than normal tissue on account of the injury received from the epithelial invasion; hence the completely necrosed tissue always appears to embrace a larger area than the epithelioma seemed to occupy when seen by the naked eye. Beyond this completely necrosed area the inflammatory process becomes less and less intense the less the tissue is invaded by the epithelial cells, but if the caustic has been applied for a long period the inflammation will be sufficiently intense to destroy all pathological epithelia as far as *b*, and almost without exception as far as *c*: that is, the disease is removed as completely as if the incision by the knife had been made at *c*, although the normal tissue has been destroyed not even as far as *b*. Of course the favorable action exends in depth as well as outward in all directions from a centre. The proof that the outlying epithelial cells are destroyed consists in the fact that the disease rarely reappears after such a condition of necrosis and inflammation has been produced.

The destruction of these outlying cells depends, in my opinion, first, upon the existence of the acute inflammatory process destroying the pathological tissue quicker than it does normal tissue, according to a general law in pathology, and especially so in this instance, as the pathological epithelia lie in the lymph spaces, and can, therefore, be vigorously acted upon by the inflammatory lymph, thus changing quickly and very greatly the previous condition under which they lived; second, that arsenic has a specially selective antagonistic action on the epithelia in this disease; and third, that the toxins, the toxalbumins, from the necrosed tissue act distinctly upon the epithelia, or, if the disease is a parasitic one, upon the organisms present.

To repeat somewhat: from the proper action of this caustic, the same result as regards removal of the disease is obtained as if all the tissue within *c* had been removed by the knife, although normal tissue has been taken from a less area than that included within *b*; that is, that the caustic is in suitable cases a much more conservative agent than the knife, and therefore it should be employed in all cases in which it is an efficient one and deformity is to be avoided as much as possible, as in all face cases, for example, especially in cases of nose epithelioma. It must not be forgotten also that this method of treatment enables the surgeon to destroy the sometimes deep-lying cancerous tissue that cannot be excised for some reason or other.

The after-treatment of the wound consists in applications of an antiseptic ointment. I use subiodide of bismuth, gr. xx. to an ounce of vaseline, allowing the dead tissue to be thrown off by the natural process and the part to heal by granulation-tissue formation, and we know how well nature can repair such gaps in the tissues. The final result is the removal of the disease, and this often with such slight deformity that the patients themselves are astonished. It is not correct to endeavor to make the wound aseptic, for if no pus organisms are present the inflammatory process will be of less duration and possibly less destructive to the epithelia, and there will also be less granulation-tissue formation, and hence more deformity.

When we come to consider some cases of extensive superficial epithelioma, such as this one, the photograph of which I now show you, and which occupies the greater part of the upper portion of the scalp, or this case occupying the greater part of the temporal region, or this example of the early form of epithelioma which occupies the entire forehead, it must be evident to all that such cases are not favorable for a knife operation, and yet they are not very difficult to treat with caustics, nor is the prognosis especially unfavorable. The exhibition of such cases must convince you that as far as they are concerned the knife is not the only remedy; in fact, that caustics ought always be used in similar instances.

It would take up too much time to describe the different forms of cancer and the different seats of the disease in which, to secure removal, a caustic is preferable to the knife, or vice versa; but in general it may be stated that when the lymph glands are involved the knife is the proper agent; and also when the disease is on such a part, for instance, as the scrotum, where a large amount of tissue can be removed without causing annoying deformity. I would not think of treating an epithelioma of the scrotum with caustics. Most cases of cancer of the penis, some cases of cancer of the ear, and all cases of cancer of the lip except the very superficial ones, require the use of the knife.

A superficial epithelioma of the lip can generally be cured by caustic applications without causing appreciable deformity afterward. I have here the photograph of a case in a well-known surgeon, and it will be seen that not a trace of deformity is to be observed. This case was treated ten years ago and was an example of a rapidly growing papillomatous epithelioma. A reference to Mr. Marsden's work will show equally surprising results. In those rare cases of glandular carcinoma of the scalp the knife should be used to remove the tumor mass and a caustic applied immediately to the whole of the wound to attack the outlying epithelia. Unless these cases are operated upon early and thoroughly the prognosis is unfavorable, as the lymph glands are invaded early in the disease.

It may be asked, if the above statements be true, why it is that nearly every operative surgeon of reputation thinks that caustics are not to be relied upon in any case of cancer, that this method is both unscientific and useless. One reason is, I believe, and that based on good grounds, that very few surgeons have ever used caustics, although aware that the advertising charlatan's cures are not by any means always fake cures; and some surgeons whom I have seen using a caustic have not applied it according to the principles of procedure I have laid down, and consequently the result was generally a failure. The proper caustic and the proper strength of that caustic must be used, and the proper amount of necrosis and inflammation produced, otherwise the result is usually injurious instead of beneficial. Unless the outlying deposits are attacked the disease will spread with greater rapidity than if no treatment had been employed, as the circulatory disturbance and nutritive condition of the outlying parts after the injury from the caustic aid the growth and extension (locomotion) of the outlying epithelia. Even when the proper caustic is used experience is required to be able to recognize when the necessary destructive action has been obtained. Mild caustics, such as nitrate of silver, carbolic acid, etc., are dangerous agents to employ, and I regard the use of them as improper and meddlesome, injuring instead of benefiting the case, for the simple reason that with them you cannot attack outlying epithelia. Chloride of zinc should not be used except to remove the papillomatous portion of an epithelioma preparatory to the use of arsenious acid, as it produces a dry necrosis and destroys normal tissue unnecessarily, and the acute inflammatory process and toxalbumin action obtained from arsenious acid are absent. The danger of reappearance is much greater after the use of this agent, and it produces too much deformity. A small epithelioma can be destroyed in a few minutes with caustic potash, but a large one should not be treated in this way unless it be a superficial one of the lip, in which case it usually acts very well indeed. About fifteen years ago I used this agent in the treatment of a gentleman from Canada, in whom the epithelioma occupied nearly one-half of the mucous membrane of the lower lip; and I defy any one to recognize to-day that he has ever had any disease of that region. With the caustic potash you get the inflammatory process and toxalbumin action, but it destroys normal tissue to such an extent that it should never be used if arsenious acid can be employed with safety.

No reliances should be placed on methylene blue, resorcin, salicylic acid, or pyrogallic acid, when we have agents of decided action and virtue.

As already stated, it is useless to apply arsenious acid to cancer covered with normal epithelium; that is the reason why in some cases, especially the pearly form of the disease, curettage sufficient to make a raw surface should always be employed before the caustic is applied. In the deep nodular form the epithelium can be destroyed by caustic potash. Some surgeons rely upon the use of the curette alone, but I am absolutely satisfied from a consideration of the pathological anatomy of epithelioma, as well as from clinical experience, that it is simply an impossibility to remove all the pathological and leave the normal tissue intact, or to know when the sound tissue has been reached. The knife is far superior to such a method. The curette can occasionally be used to remove the mass of a large epithelioma in order that the arsenious-acid paste can be applied near the peripheral part of the growth.

If the surgeon has observed only cases treated in some of the ways I have just mentioned as being imperfect, useless, or injurious, then I can understand his belief in the knife as the only proper agent to be employed; but if he were to choose his cases and in the treatment of them follow precisely the principles and methods I have just given you, he would recognize that the proper treatment for a given case depends upon the kind of epithelioma, its size, its method of extension, and its location, and that for the majority of the cases of cutaneous cancer the caustic method properly employed gives the best results both as regards the removal of the disease and the minimum of deformity from the operation.

It is just as important that the pathological anatomy of the disease, the normal anatomy of the part, and the technique of the operation be well known by the operator as if the case were one of visceral cancer or of an abdominal tumor. Neither the knife nor the caustic should be blamed for the faults of the operator. There are some cases of cutaneous cancer that are incurable when first seen by the surgeon, the disease having progressed too far; other cases are fatal because the physician or surgeon has dallied with the case, relying upon ineffective or injurious agents; and finally not a few cases have a fatal termination because the patient is not seen often enough, nor for a long enough period after treatment has been commenced. I know of more than one patient I have lost because I failed to insist upon his remaining under my observation. In this respect medical men make the worst patients, and in the end are always dissatisfied if the disease reappears. A case should not pass out of observation for at least one year, whether operated on by the knife or by caustic, as there is always a possibility of reappearance which demands immediate attention.

In those cases in which there is a tendency to the formation of epitheliomata the complete removal of one tumor does not prevent the formation of new ones, and the treatment in this case is not deemed unsuccessful on account of the recurrence. These cases require watching as long as the patient lives.

It can be safely said that if cutaneous epithelioma is seen early and treated properly, either by caustics or the knife as the case demands, the disease is anything but the necessarily fatal one too generally believed by the medical profession, a belief that has been the cause of much dangerous advice to patients.

Finally, if the profession will study this subject as I have now presented it, and the works on surgery will represent facts as regards the results of different methods of treatment more than individual experience, the advertising "cancer specialist" will not be treating cases that should belong to the regular profession. These "specialists" will, however, continue to treat them just as long as the laity have proof that a caustic has cured many a case that has already been operated upon by the knife on orthodox principles, because the surgeon believed that "outlying deposits could be removed by the knife only and not by caustics."

Conclusions.—1. At present we know of no drug, animal extract, serum, or toxin, which, given internally by any avenue of the body, can be relied upon for the cure of cancer of any part of the system.

2. That the statement that the knife is the only reliable agent in the treatment of cancer is not correct.

3. That certain caustics judiciously chosen and properly applied may attack deposits of the growth inaccessible to the knife, and in these cases should be employed even if the knife is necessary to prepare the way for their use.

4. That in some cases both the knife and caustics should be used, and in some other cases curettage, followed by a caustic, is the proper procedure.

5. That the majority of cases of cutaneous cancer can be removed with the greatest certainty and with least deformity by caustics, provided the patients are seen before the lymphatic glands are invaded.

6. That the knife should be used when the lymphatic glands are invaded, and also in some other cases of external cancer.

THE CARDINAL PATHOGNOMONIC SIGN OF FRACTURE OF THE LOWER END OF THE RADIUS (COLLES').

By MARTIN W. WARE, M.D.,

ATTENDING SURGEON, GOOD SAMARITAN DISPENSARY, NEW YORK.

The erroneous teaching of the invariable occurrence of silver-fork deformity in Colles' fracture is still fostered by this ever-repeated stereotyped expression in the current text-books of surgery and special treatises on fractures, which accord undue prominence to this sign.

In an experience of three hundred cases of fracture of the lower end of the radius, this sign was encountered in less than ten per cent. of the cases, and for the establishment of the diagnosis in all of these instances reliance was placed on a far more logical and anatomical sign, which a careful perusal of the literature has convinced me is, to judge by its omission, unfamiliar to the greater number of surgical writers.

A comparison of the outlines of what various authors concede to be silver-fork deformities shows widely different impressions to be gained, and this be it said without belittling the significance of this sign when present; yet, granting that these variations may represent different degrees of this fracture, so variable and inconstant a factor ought not to be accepted as paramount in the diagnosis of Colles' fracture. It would, therefore, seem desirable to rely upon a certain and ever-constant anatomical landmark analogous to the Roser-Nélaton line, or to the bicondylar olecranon relations at the elbow. That such a landmark exists, a palpation of the topographical prominences of the normal wrist shows. The styloid of the radius is at a lower level than the styloid of the ulna. This is always the case, normally differing in degree according to the development of bones, being more marked in males than females, less so in infancy. With the hand in the prone position and on the same plane with the bones of the forearm, this sign is most readily ascertained by then impinging the thumb and index finger against the styloids; and, projecting a line between these two points, it will take an oblique course slanting to the radial side. This is the line I would take advantage of in interpreting injuries about the wrist joint. As, roughly estimated, in ninety-five per cent. of the fractures of the radius there is impaction, the shaft must be shortened, but this is so slight in the majority of instances that it cannot be measured with the tape.

It has been my experience that silver-fork deformity is the exception *par excellence* in Colles' fracture. More frequently many of the other signs, particularly localized tenderness alone, pointed to a suspicion of a fracture, but in every instance the one logical fact of the levelling of the styloids only justified the diagnosis. An estimate of the existence of the levelling or elevation of the radial styloid should be the first manœuvre in ascertaining a fracture, thus precluding any further manipulation until reduction is performed. It would suggest itself that this relation of the styloids ought to be an index as to proper reduction; this is but relatively so, as an absolute restoration of the normal relation of the styloids is impossible in the greater number of instances; at the best an approach thereto can be aimed at, since the comminution at the line of fracture has often been so great that even when the impaction has been broken up the subsequent absorption of bone causes a shortening which is again apparent in the relation of the styloids. The converse, however, may be held, that when there is an elevation of the radial styloid and a history of injury such as precedes fracture of the wrist, even in the absence of any other deforming signs, a verdict of previous Colles' fracture can be rendered. The persistence of the altered relations of the styloids is not to be interpreted as interference with the growth of the bone, for it occurs even after the age limit at which epiphyseal junction has taken place. Once I fell into error by crediting this altered relation to a fracture, whereas syphilitic epiphysitis was solely responsible for the condition.

I have tested this sign these past four years, and so unfailingly has it been present that I now, in conjunction with the corroboration obtained from some older literature, would accord it the dignity of the cardinal pathognomonic symptom of Colles' fracture.

The only mention of this sign in any English textbook occurs in Stimson's treatise on "Fractures and Dislocations." Both in the first and second editions he says: "If the surgeon marks the positions of the styloid processes by pressing the end of the finger into the side of the joint below and against the end of each, he will see that of the radius has risen so that instead of being a quarter of an inch lower (nearer the hand) than that of the ulna, as it usually is, it has risen to the same level or even above it." In the text these words are subordinated to other remarks bearing on this fracture, and in the paragraph on diagnosis this sign is entirely neglected, and sole reliance placed when in difficulties on localized tenderness. Recently, however, Stimson in connection with his radiographic studies called attention to the fact that "the prominence of the ulna was due to the ascent of the radius." Nowhere in the German literature is cognizance taken of this phenomenon.

In the *Archives of Roentgen Rays* (vol. iv., p. 22, 1899), Mr. J. Lynn Thomas says: "A line at right angles to the radius and ulna should always be drawn (when studying Roentgen photograms of old injuries to the wrist) immediately on the hand side of the articular surface of the ulna. This line is the only safeguard for rightly interpreting old healed-up fractures of the lower end of the radius. The whole of the articular surface of the radius when in its normal position is on a plane situated on the hand side of the diagnosticating line. When the radial styloid is on a level with that on the ulnar it is considered to be in itself of such importance as to establish the diagnosis of a Colles' fracture, and is known as the 'signe de Langier' in France."

Malgaigne looked upon the localized tenderness as a pathognomonic symptom.

Gosselin[1] says: "In the absence of the silver-fork deformity, what is above else the principal element in the diagnosis in fracture of the lower end of the radius, which I depend upon to establish the nature of the lesion . . . I have found that in such instances the styloid apophyses are almost on the same plane; in other words, that they are situated on a plane forming two right angles at the junction of a plane passing in the line of the axis of the forearm. You know, in fact, that in the normal state the radial apophysis is situated a little lower than the ulnar, and that a plane joining these two is obliquely intersected by the axis of the forearm."

Still more pertinent is the following quotation from Richet,[2] writing in 1882: "If you would avail yourself of palpating on the skeleton, the bony prominences in which the bones of the forearm terminate, viz., the styloid apophyses, one is struck by a peculiarity which is not mentioned by the classic authors, and which I have repeated in my clinics for ten to twelve years. . . . Embracing the apices of the styloid processes between the thumb and index fingers in a healthy wrist, one notices that these prominences are not on the same level, the radial being much lower than the ulnar. In a fracture at the wrist, on the contrary, one can see that the styloids are on the same level and that the radial apophysis is even higher. This is a sign that never fails. Moreover, since these prominences are well marked, being superficial, it is always possible, I should even say easy, to feel them, and consequently to attach the importance to them to which I have just alluded. I shall go even further, and I shall say that the confirmation alone of this deformity suffices to affirm this diagnosis."

Of still more recent date is the opinion quoted from the "Traité de Chirurgie"[3]: "In consequence of the penetration of the fragments the styloid apophysis of the radius, which normally descends below that of the ulna, ascends to the level of the latter. This is known as the 'sign of Langier.' It is of the greatest importance, and suffices of itself to establish the nature of the lesion."

In estimating this sign the normal wrist must always be taken in comparison. This sign antedates the use of x-rays; in addition it has stood the test of them, and so conspicuously does this altered relation of the styloids figure in skiagrams, that just herein lies the greatest confirmation of its practical service.

Its value may be summed up as consisting in the facility of its clinical application, wherefore x-rays may be dispensed with, and the patient spared the needless suffering of manipulation to learn the nature of the lesion. It rests on sound anatomical data, which makes it a logical sign. It is in part an index as to what has to be aimed at in reduction, and it is also ever after a landmark of the site of the healed fracture.

For these reasons I accord it the dignity of "the cardinal pathognomonic sign of Colles' fracture," in the hope that a consideration of the value of this sign will further the recognition and incidentally the treatment of a larger number of fractures.

LOCOMOTOR ATAXIA.[2]

By B. C. LOVELAND, M.D.,

SYRACUSE, N. Y.

LOCOMOTOR ataxia, posterior spinal sclerosis, tabes dorsalis—these are synonyms for a progressive degeneration of the spinal cord, marked by more or less of anæsthesia, analgesia, paræsthesia, and inco-ordination, and later muscular paralysis. The only apology I have to offer for bringing such an old and well-studied subject before this society is that in its early or pre-ataxic stage it is often overlooked, while its various symptoms then presenting are treated as independent phenomena, and what hope there is in treatment depends largely on its early recognition.

It is not within the province of this paper to go into a detailed study of the etiology of this disease, and yet a few words as to its cause, or causes, should not be omitted. It is pre-eminently a post- or para-toxic degeneration. The toxic infection which has been found to furnish the soil for the growth of this form of degeneration in a vast majority of cases is syphilis. So frequent is the specific history in these cases that many authorities regard the exceptions as incomplete histories, and not as posterior sclerosis without the luetic infection. The percentage of cases with syphilitic histories varies with different authors from eighty-seven per cent. to ninety-three per cent., and yet it is conceded that such toxic conditions as ergotism and pellagra may furnish the predisposing cause, and there may possibly be others added to the list as our observation increases.

Pathology.—While the etiology of tabes dorsalis in most cases is inseparable from syphilis, the pathology is not the pathology of syphilis. It has a distinct pathology of its own. As one author has graphically expressed it, "The blackened and charred stumps and seared grass are not fire, but they mark the track where the fire has been." So posterior spinal sclerosis is not syphilis, but it marks the devastation which follows in its wake. It is a true degenerative process, beginning, according to various authors, either in the peripheral sensory nerves or in the ganglia on the posterior roots, which contain the trophic centres controlling these nerves. The degeneration is fibrous in character, compressing and finally obliterating the true nerve structure. Its course is from the periphery toward the centre of the nervous system, the degenerative process following each nerve affected from its peripheral end through its entire length, even after it enters the cord, till it reaches the nerve cells into which the afferent impulse is discharged, following the order of degeneration observed by Waller after the section of an efferent nerve fibre. The number of nerves at first involved may be small, and it may begin its work at the lower, the middle, or the upper or cervical sections of the cord, and the early symptoms will vary accordingly. As the disease progresses, more and more nerve fibres are implicated, and the hardened or sclerotic area in the cord is correspondingly increased. The same degeneration may also involve the medulla, and in certain cases it attacks brain structure, though rarely. It may be said, however, that the pathological change found in the brain in paretic dementia is identical in character with that found in the cord in tabes. It seldom if ever seems to attack the various sections of the cord with equal force at the same time. If the process is actively progressing in one section, it will check in another. The posterior columns of the cord are the ones affected, as the name implies, though in some advanced cases the degeneration spreads over into the lateral columns.

[2] Read before the Onondaga Medical Society, March 6, 1900.

Symptomatology and Diagnosis.—It goes without saying that in this disease, in which the pathological changes are confined almost entirely to the sensory nerves, the subjective symptoms, or the feelings described by the patient, hold a strong place among diagnostic signs, but should always be followed up and verified, or set aside, by the physical signs. Among the most frequent symptoms complained of are a feeling of general weakness, a tendency to stagger at night when getting out of bed, a feeling of numbness in the limbs, a velvety or padded sensation in the bottoms of the feet, and sharp, shooting pains in the legs or lower part of the abdomen. Very early in the history of the case the patient will occasionally mention unusual sexual excitement; a little later, and comparatively early in the case, partial or complete impotence follows, and is often referred to by the patient as a result of his excesses, but from the pathology of the disease it will be otherwise accounted for. There may also occur as early signs the various crises so called, most commonly of the stomach, which consist of sharp, extremely painful attacks, sudden in their onset, equally sudden in their subsidence, and baffling relief by any of the ordinary remedies. The gastric crises are accompanied by severe and intractable vomiting, increased by anything taken into the stomach. Entire rest to the stomach and the use of hypodermic injections of morphine may be required. The laryngeal crisis is less frequent, but quite as distressing, by reason of its paroxysmal and uncontrollable coughing and dyspnœa. Occasionally hemiplegia is an early symptom, recovering after a short time. Sometimes also we see a paralysis of single muscles, notably those of the eye, also transitory in nature. The pupils may be unequal in size; may respond to accommodation, but not to light (Argyll-Robertson symptom); or may be sharply and firmly contracted. Sometimes among the early symptoms we find a contracted visual field, a narrowed or diminished color field, and optic neuritis or atrophy. Muscular strength may remain good, and the ataxic gait may not appear for a long time, or possibly never appear in rare cases. Among the cerebral symptoms noted early are insomnia, vertigo, depression, more rarely melancholia, and very rarely general paresis. Bearing in mind that the degenerative process may begin in any part of the central nervous system, the early symptoms will vary in their manifestations according to the portion of the cord or medulla affected. The practical identity of the pathological processes in paresis and tabes would almost warrant the statement that the diseases are essentially one, except that in the former cerebral symptoms predominate, while in the latter spinal symptoms have the lead. No one symptom can be called pathognomonic, but any of the symptoms noted should prompt investigation, and if a fixed pupil as regards the light reflex, absence of knee jerk, and lightning pains are present, a diagnosis may be made with certainty, even though the gait is not ataxic.

Prognosis.—Of course in a disease based on such fixed pathological conditions a cure, or the restoration to normal conditions, is an impossibility, therefore we must be satisfied with relief of distressing symptoms, and must consider as a success any treatment which will check the progress of the disease. The length of time required for this disease to run its course is in different cases from three to thirty years, and in most cases death ensues from intercurrent affections. By some authors it is divided into two classes, severe or malignant, and benign. The severe cases run a more rapid course and manifest a more persistent tendency to progress than the benign cases. An early diagnosis adds much to the favorableness of the prognosis, for all that is done must be by way of preventing the progress of the degeneration, as reorganization of the diseased tissue cannot be accomplished.

Treatment.—Much of the treatment must be directed toward relieving the distressing symptoms and increasing the patient's general health, and may be divided into medical and hygienic, including mechanical and hydrotherapeutic.

The medical treatment at first should be directed to the relief of the lightning pains if they exist, and for that purpose powders containing phenacetin gr. v., citrate of caffeine gr. ss., given as occasion requires, will be found useful. Next considering the probability of a specific history, and the possibility of effusion in the spinal canal as a provoking cause, it is well to use some pronounced specific treatment for a few weeks, unless you are sure that such a course has been taken quite recently. If good results follow, such a course may be repeated every three months. It must be borne in mind, however, that the general effect of heavy doses of mercury or iodide of potassium is depressing to the nutritive system and may do harm; therefore, if no positive good results, they are best abandoned. Strychnine and tonics generally do not hold the strong place that they are supposed to hold in the treatment of many of the functional nervous disorders. Any specially troublesome symptom may require special medication.

The hygienic treatment includes, first and most important, rest. This should be thorough, and it is sometimes advisable to institute a systematic "rest cure." At all events the patient should refrain from any exertion which would exhaust him, and also from worry and anxiety. Next in importance, and at present growing in popularity, is exercise. This should be so prescribed as to get the patient to perform with care and precision, aided by sight, those motions which, owing to his inco-ordination, can no longer be done automatically. It is not necessary here to give the movements in detail which have been prescribed, as any one with ordinary ingenuity can work out a reasonably useful set of exercises. Massage, for its general effect in aiding tissue change, is often very useful, and the same may be said of electricity. The faradic current for general application helps to prevent the atrophy of muscles, while the galvanic current applied after the manner called central galvanization, or a simple spinal application, often helps to improve the circulation in the spine. Stretching the spine has been found to give some relief to the pains, and also, temporarily at least, to increase the sexual vitality. Stretching of the spine was at first accomplished by suspension in the Sayre apparatus, but the same results without the dangers can be obtained by flexing the body strongly on itself. The modus operandi advised by Church and Peterson is to seat the patient on the floor, and ask him to bend forward as far as possible, keeping the knees straight, while the physician presses down on his head, graduating the pressure according to his judgment. This position is supposed to increase the size of the openings between the vertebræ through which the nerves and blood-vessels pass, thereby increasing the circulation in the spine. By the method of extension in one case I was surprised to see the patient, who had for a long time been obliged to use two crutches to get about at all, so far improve that he went to work in a shop, and was able to walk back and forth to work by the aid of one cane, sometimes two, and the improvement remained for several months while he was where I could observe him. The warm or tepid bath is also of much use in relieving the pains, and is best given as follows: A tub is filled two-thirds full of water at 92° to 94° F.; the patient, disrobed, sits in the tub for twenty minutes. He is then taken out, wrapped, without drying, in a flannel blanket, and laid on a couch, while an attendant gently rubs the limbs through the blanket for the space of another twenty minutes.

We are all sufficiently familiar with the disease in its later or more pronounced development, but I shall report for illustration one or two cases that belong to the benign variety.

CASE I.—Hon. J. Q. A. B——, October 26, 1897; age, fifty-five years; weight, 160 pounds. The disease had been recognized ten years before, when he began to have the padded feeling in his feet. He had been much depressed. He was of a constipated habit, and his lancinating pains had been most severe and unyielding.

Present condition: No knee reflex was obtained; Argyll-Robertson pupil; the gait was not ataxic; the Romberg symptom was not marked, but slight; there was analgesia on the outer surfaces of both legs and outside of both arms below the elbow; the lancinating pains were frequent and severe. The diagnosis was plain, although there was no sign in his walk.

Treatment: He was given proto-iodide of mercury, gr. $\frac{1}{6}$ t.i.d., and a pill containing strychnine, gr. $\frac{1}{50}$, after each meal, together with the warm sitting-bath described above. As a result, his spirits had much improved, and he had escaped the lancinating pains for nearly two weeks when he left my observation. From the fact that no systematic and prolonged treatment had been pursued, I think that this case was a benign one, and stopped its progress spontaneously. The relief of pain following the treatment described was, however, very marked, and may perhaps be credited to the treatment.

CASE II.—Mrs. F. A. G——, forty-four years old; June 3, 1898. Her history was as follows: She was married and had two children, the youngest seven years old; no miscarriages. She had had malarial fever each spring for several years. Heredity was good. She began to have shooting pains in her limbs two years ago, and was treated for sciatica, and later for neuritis. She became sleepless, greatly depressed, and suspicious, especially of her husband. She cries a great deal. She eats little; has lost about thirty pounds of flesh. She still has severe pains in her legs.

Physical examination: The tongue was coated; the pulse and respiration were normal; the bowels were regular. Urine, specific gravity 1.030, acid, with oxalates. Blood showed hæmoglobin eighty per cent., red corpuscles 5,680,000. There was no knee reflex. She had Argyll-Robertson pupil. She walked well, but showed slight unsteadiness when the eyes were closed. Diagnosis, tabes in the first stage.

Treatment consisted in removal from family, with rest, massage, warm bath, and bromide and salicylate of sodium of each gr. x., well diluted, three times a day. Her pains improved rapidly; sleep returned, and the depression disappeared to a large extent. Proto-iodide of mercury gr. $\frac{1}{6}$ before each meal, with salol gr. v., and phenacetin gr. iiss. when required for pain, were substituted for the bromide and salicylate of sodium. At the end of a year she reported as having been practically free from pain nearly the whole period. She had continued the proto-iodide a large portion of the year. On examination she showed a slight knee reflex, better in her left knee, and a very slight reaction of one eye to light. Other signs had remained the same, except that she had gained some flesh. This case it seems to me profited by a fairly early diagnosis, and received much benefit from treatment, though it was not of the worst type as regards rapidity of progress.

Cæsarean Section in the Moribund. — Anton Prokess says that in sudden death the results of section are bad, because the fœtus dies before the mother. It has therefore been suggested not to wait for the actual death of the mother before operating. A case is added to the statistics of successful performance of Cæsarean section under these conditions.—*Centralblatt für Gynäkologie*, March 3, 1900.

The Pathogenesis of Cyclic Albuminuria.—Dr. Rudolph says the centre of disturbance in this affection is still unknown, and there is no sure method of cure. The best one can do is to spend a number of months in Southern climates. A case is related of a boy who showed albuminuria when active, but which disappeared when he was in bed. Still rest did not effect a cure. Two girls recovered without the rest cure. The various theories of causation are reviewed. —*Centralblatt für innere Medicin*, March 3, 1900.

Expanded Metal, a New Splint Material, Especially for Use in Military Surgery.—C. Hubscher recommends a new metallic substance used in building and largely employed in the Paris Exposition structures, for use in making splints with plaster or cement. It can be moulded to any part, and padding is scarcely necessary. Its advantages in field surgery are its lightness and ease of transportation.—*Centralblatt für Chirurgie*, March 3, 1900.

Electrolysis as a Means of Curing Chronic Glandular Urethritis.—George Walker has employed the method learned in Kollmann's clinic and found it satisfactory chiefly when the glands of Littré and crypts of Morgagni are involved. The treatment was originated by Oberländer, and consists in inserting a fine needle into each opening. A decided urethritis is set up by the process. Strictures have resulted, but can be avoided by care in application.—*Maryland Medical Journal*, March, 1900.

Changes in the Skin in Paralysis Agitans.—Robert Reuling speaks of the addition to our knowledge of pathology by Fraenkel's discovery of changes in the skin in paralysis agitans. The frontalis symptom recently described is best brought out by getting the patient to look upward for two minutes and then downward. The deep wrinkles require three or four minutes to disappear. Fraenkel thinks it due to thickening of the skin and loss of elasticity, though there may be little change in appearance. A case is reported with microscopical examination showing increased connective-tissue growth in the true skin and subcutaneous connective tissue. Skin changes were found in four out of six cases examined, but no direct relationship is traced between them and the tremor. The author regards them as trophic phenomena.—*Maryland Medical Journal*, March, 1900.

Surgery of the Lungs.—A. Parozzani, referring to operations upon wounded lungs, says that owing to their gravity in patients already weakened by traumatism, to the action of chloroform upon respiration performed by one lung only, and of the possible induction of purulent pleurisy, surgical intervention should be resorted to only in cases in which the blood comes out in spurts, and there is forcible blowing in the bronchi. In other cases rest in bed in a half-sitting position, liquid diet, an ice-bag on the chest, and injections of morphine and ergotin, and caffeine for cardiac adynamia will be the best treatment.—*Rivista Medica della Regia Marina*, December, 1899.

Modern Surgical Treatment of Infantile Spinal Paralysis.—A. Codivilla gives a long theoretical discussion of the methods to be adopted in the treatment of muscles left in a condition of contracture by paralysis. His work is based upon the results of forty transplantations and plastic operations on tendons.—*Il Policlinico*, February 15, 1900.

Exstrophy of the Bladder from Ulcerative Destruction of the Scar of a Suprapubic Cystotomy.—L. Kolipniski relates a unique case in a man after suprapubic removal of calculi. After about four years there was a swelling about the cicatrix due to urinary infiltration. An incision was made, but sloughing occurred and was followed by protrusion of the superior and posterior walls of the bladder. Death took place on the fifth day.—*Maryland Medical Journal*, March, 1900.

Movements, and Relative Change of Form and Position in a Human Fœtus of Five Months.—Fabio Rivalta incised the thorax of a five-months fœtus, and found the heart pulsating at the rate of twenty-four times to the minute. The contraction of the four heart cavities was not simultaneous but successive. Although there was no blood current, the movements of rotation of the heart in relation to its longitudinal and transverse axes, the uplifting of the apex, and the downward drawing of the apex of the pulmonary artery and base of the aorta were exactly the same as under physiological conditions.—*Rivista Critica de Clinica Medica*, February 24, 1900.

Causes for the Weakened Virulence of Vaccine in Hot Climates, and the Remedies Therefor.—M. Hervieux gives the causes of the attenuation and destruction of the power of vaccine, as heat, especially damp heat, winds such as the sirocco, and age. Vaccine, as soon as prepared, should be placed in a refrigerator, transported in one, or else wrapped in wet cloths, kept moist and placed in a draught of air in the shade. In the hot seasons it should be used as soon as possible after its reception.—*Bulletin de l'Académie de Médecine*, February 13, 1900.

Mucous Polypi of the Nasal Septum.—Oliviero Barrago-Ciarella reports a case of this rare affection. The left nasal fossa was completely filled with the polypi; in the right one was an oblong tumor, about the size of a bean, pedunculated and inserted on the septum. It was at once removed by the use of Wilde's snare. There was no hemorrhage. The chief symptoms given by the neoplasm were headache of the right side and obstruction of the nose, sometimes to a slight extent, sometimes total.—*Giornale Internazionale delle Scienze Mediche*, January 15, 1900.

A Rare Complication of Progressive Locomotor Ataxia.—P. J. de Bruïne Ploos van Amstel believes, from the literature on the subject and from personal observations, that the following conclusions can be drawn: (1) Progressive locomotor ataxia is not an essential malady, but a sequel of syphilis, and may be considered either a "nachkrankheit" or a post-syphilitic intoxication; (2) aneurism and insufficiency of the aorta in the ataxic patient are not accidental complications, but they are also caused by syphilis; they are also the "nachkrankheiten" of syphilis.—*Lyon Médical*, January 14, 1900.

Acute Rhinitis.—W. S. Fowler says that from the notes of the last hundred cases of acute rhinitis which have passed through his hands, seventy-six showed clear and unmistakable constitutional symptoms as the cause; six were due to external local irritations, mostly occupation irritants; sixteen were recorded tentatively as due to contagion. The author has found that treatment addressed to the underlying cause has given the greatest success, and thinks that many physicians have fallen into a habit of treating the symptoms only, neglecting to give proper value to temperament and diathesis.—*Southern California Practitioner*, January, 1900.

Chyliform Ascites.—F. Micheli and G. Mattirolo describe a series of experiments conducted for the purpose of ascertaining to what is due the opalescence noticed in certain ascitic effusions in which there is but little fat. Their conclusion is to the effect that in many cases lecithin is the cause of this milky appearance.—*Rivista Critica di Clinica Medica*, January 27, 1900.

Total Ossification of the Choroid; Sympathetic Irido-Choroiditis; Sanguineous Infiltration of the Cornea; Blindness.—Carlo Fruginele reports a case in which blindness of one eye, due to corneal ulcer, was followed eight years later by sympathetic inflammation of the other eye. A slight blow received upon the latter in its enfeebled condition must have caused laceration of some blood-vessel, for an infiltration of blood followed. Total blindness was the final result. —*Gazzetta Internazionale di Medicina Pratica*, February 15, 1900.

Lumbar Puncture in Pediatric Practice.—Carlo Giarrè considers this procedure valuable for the diagnosis of meningeal hemorrhage, serofibrinous, purulent, and tuberculous meningitis, the extracted fluid differing in its physical and chemical properties from that obtained in some other conditions. With increased knowledge of the pathogenesis of acute serous meningitis and the nervous troubles known as "meningism," it is probable that lumbar puncture will give better therapeutic results than any other measures known. Quincke's operation is especially indicated in many of the diseases observed, especially in infancy.—*Rivista Clinica di Critica Medica*, February 3 and 10, 1900.

Chorea of the Larynx.—A. Onodi says that this affection has nothing to do with general chorea. He briefly describes our present knowledge concerning the latter affection, and reviews the literature which has appeared since Ziemssen's article upon chorea of the larynx so-called, in 1875. A special analysis is made of the case reported by Preysz, which is the first publication concerning the pathological alterations of the vagus and recurrent nerves in this affection. Onodi collates the views of several prominent laryngologists, and believes that the term "chorea of the larynx" should be given up, as most if not all of the cases hitherto thus described can be included under other clinical groupings, and because the condition is not a true chorea. Some are cases of hysterical cough, some are phenomena of imitation, and others are simply spasmodic habit. He would admit the designation for some cases of "choreiform movements of the vocal cords." A valuable bibliography is given, and also a discussion of the paper before the Medical Society of Budapest.—*Revue Hebdomadaire de Laryngologie, etc.*, January 13, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, March 31, 1900.

INTER-STATE RECIPROCITY IN MEDICAL LICENSING.

THIS is a somewhat complicated subject, and is hedged in by so many intricate points that a lucid and wholly intelligible presentment of its "pros and cons" is a far from easy task. Any man of ordinary intellectual capacity can understand that until there is a uniform standard of medical education in all the States, it would be manifestly unfair to place the graduates of the various schools throughout the country on a perfectly equal footing. The States which maintain a high standard of medical education have undoubtedly the right to protect their own physicians. In fact this course is incumbent upon them. Therefore the State of New York, for instance, in which such a standard is insisted upon, requires that outside physicians, without any discrimination, who may wish to practise within its borders, shall undergo a further examination as a proof that they possess the requisite medical knowledge.

This decidedly just procedure is, however, a matter for grave complaint to many regular physicians from other States, some of whom have raised the question as to its legality, contending that the Constitution of the United States by its very words protects them from the necessity of being subjected to this further examination. The provisions referred to read thus: "Article IV., Section 1. Full faith and credit shall be given in each State to the public acts, records, and judicial proceedings of every other State. Section 2. The citizens of each State shall be entitled to all privileges and immunities of citizens in the several States." To deal with these points in all their ramifications would necessitate the writing of a pamphlet, but at the same time it is possible to indicate briefly why these constitutional provisions do not exempt the outside physician from the need of complying with the particular regulations of the State to which he goes. The "full faith and credit clause," so called, cannot be relied on in support of the contention, as this clause is construed only to refer to the judicial proceedings of the several States. A physician's license is not such a judicial proceeding as the clause of the Constitution contemplates. Therefore there is no need to dwell upon this phase of the matter at greater length.

A more serious question, however, is involved in the words included in Section 2. It is natural for a physician duly licensed in another State to ask why the assumed privileges and immunities as a physician of that State do not protect him from the necessity of passing a further examination when he comes to New York to practise. A full comprehension of this question in all its bearings depends upon a proper understanding of the history of the United States. Before the several States adopted the Constitution of the United States in 1789, each of these several States was a complete independent sovereign. When the Constitution was adopted, the national government was thereby created with certain powers; and those powers resulted from the surrender by the individual States of certain features of their own sovereignty. In order that the sovereignty of the different States should not be altogether merged in that of the central government, the following amendment was added to the Constitution: "The powers are not delegated to the United States by the Constitution, nor prohibited by it to the States respectively or to the people."

It has thus resulted that the individual States were in no wise divested of their sovereignty by the adoption of the United States Constitution except so far as that instrument shows an express surrender of their sovereignty. In all other respects they have retained it. Every State, for example, has retained unimpaired its original power to make police regulations, included among which is the right to make laws concerning the regulation of the practice of medicine. This proposition has been fully determined by the supreme court of the United States, and the courts of the individual States have uniformly sustained the power of their States to pass legislation of this character. Consequently the State of New York is undoubtedly within its rights in requiring physicians to pass an examination before they can be licensed or registered. When a physician comes from another State to New York he brings with him all the rights which he enjoyed "as a citizen," but his right to practise medicine in another State never was possessed by him merely because he was a citizen. He enjoyed that right because he had conformed to the regulations and laws of the State in which he lived. The fact of being a citizen of New York confers no right to practise medicine merely because of the citizenship. In a few words, if a man goes to another State he carries with him only his bare rights as a citizen, and must conform to the police laws of any State he may choose to enter.

These views have been upheld times without number by the supreme court of the United States. There are other solid arguments in support of the contention that every State possesses the indisputable right to regulate the practice of medicine within its jurisdiction, but these are too lengthy to be presented in a single article. The pith of the matter has been given, and enough has been said to exhibit the situation in a clear light. The laws of New York State were designed with the intention of excluding physicians whose medical education did not reach the standard required of its own citizens. Probably when some kind of uniformity in medical education has been reached in all or even in a majority of the States of the Union, the legislature of New York State may see fit to revise or modify its present stringent regulations relating to medical practice, but until that day arrives it would be in a high degree foolish as well as unjust to alter the existing condition of affairs.

NEW DISINFECTING STEAMER FOR HAVANA.

The United States Marine-Hospital service is about to despatch to Havana a new disinfecting steamer designed under the supervision of its bureau. The *Sanator*, the appropriate name of the vessel in question, has just been completed in Philadelphia, and would appear—from the description given of her in *Marine Engineering*, March—to be up-to-date in every particular. It is claimed for her that she is the most complete floating disinfecting plant in the world. The value of a floating disinfecting plant has already been amply proved, the efficient services rendered by the disinfecting barge *Protector* of the Marine-Hospital service, in disinfecting troops and troop ships returning from Cuba in 1898 during our war with Spain, being a case in point.

The disinfecting equipment of the *Sanator*, as a matter of course, is of the most modern and perfect type. There are a formaldehyde apparatus, sulphur furnaces, and bichloride of mercury apparatus. Probably there is scarcely a harbor of the world where the services of such a vessel as the *Sanator* are more urgently required than that of Havana. Doubtless, however, the efforts being put forth on land and sea will have the effect of regenerating from a sanitary standpoint that most unsavory town, and in wholly removing the stigma which is now attached to its name. In this good work the *Sanator* should play a prominent part.

INTERNATIONAL ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, ARTS, AND EDUCATION.

The suggestion has often been made within recent years that the formation of such an association would greatly tend to the furtherance of science, arts, and education, but until the meetings of the British and French associations for the advancement of science at Dover and Boulogne in 1899 no steps had been taken to bring these ideas to a practical conclusion. At the aforesaid meetings, however, the resolution was come to that the time was ripe for action, and with this end in view influential committees of Englishmen and Frenchmen were formed, the first meeting of these joint committees being held in London in October, 1899. M. Léon Bourgeois was elected first president, and Paris was fittingly chosen as the seat of the inaugural meeting of the association.

The association, according to a pamphlet published on the subject, has been legally incorporated in Britain and in France; offices have been opened in Paris, London, and Edinburgh, and in other European cities; while Professor Geddes, secretary to the British section, has spent upward of two months in the United States endeavoring to enlist recruits. His labors would appear to have been attended with a fair measure of success, as he announces that a committee has already been formed in Chicago to carry on the work of the association, and to co-operate with those already existing in Paris, London, etc. Similar committees have been organized in Boston, Philadelphia, New York, etc. W. T. Harris, LL.D., United States commissioner of education, has also set the seal of his approval upon the scheme, and in a letter to Professor Geddes signifying the same he makes use of these pregnant words, the truth of which will strike every unprejudiced person: "It is evident that intimate relations among the educated classes lead to solid, mutual benefits; while on the other hand it is a matter of common observation that the meeting of the uneducated masses of one nation with those of another nation often results in misunderstanding and mutual distrust."

The organization of the American group has not as yet been decided upon. The proposal has been made that its members should join hands with the British, but these matters of detail will be settled later. There can be no doubt that nothing but good can come of an association formed upon lines so broad.

TUBERCULOSIS AMONG THE POOR.

The unhealthy conditions under which a very large proportion of the working classes are compelled to live is a matter too notorious to be treated lightly by any intelligent person. The subject, especially in these days, has been taken as the text of many a medical sermon, and the importance of both preaching and putting into practice everywhere the gospel of cleanliness has been so constantly dinned into the ears of members of all grades of society that even the most selfish or careless plutocrat is being forced to the conclusion that the affairs of the poor and the need of hygienic dwellings for them are questions not altogether outside his sphere of interest. Municipalities and house-owners are becoming daily more and more impressed by the gravity of this aspect of the situation, and are beginning, though tardily in some instances, to recognize and to assume their responsibilities with regard to the physical welfare of their fellow-men.

As has been pointed out times without number, insanitary houses are not only a fruitful source of danger to those who live in them, but a standing menace to the inhabitants of the entire neighborhood. For example, leaving out of the question the well-known fact that a virulently contagious disease will spread with the greatest rapidity amid a filthy environment, the foremost physicians and scientists hold the view that tuberculosis is undoubtedly disseminated by the agency of dirt and overcrowding and of unsalubrious surroundings generally. The extent to which supporters of this theory carry their belief varies considerably, but all are agreed that the proper housing of the poor will play a conspicuous part in checking the inroads of tuberculosis, and that until the methods prevailing in many large cities undergo a radical change the disease will continue to flourish. The Charity Organization Society of New York has of late been attacking with praiseworthy zeal the disgracefully lax manner in which the tenement district of New York City is ordered in respect to the unhygienic state both of the old buildings and of the new. Attention has been called on several occasions in the Medical Record to the fact that the portion of New York in which the poor most do congregate is probably more densely populated and constructed upon worse sanitary principles than is a similar district in any other part of the civilized world. It is said that there are at present over forty-four thousand tenement houses in the old city of New York, and new tenement houses are being erected at the rate of about two thousand a year.

The Charity Organization Society of New York has recently published an address which was delivered by Dr. S. A. Knopf before the Tenement-house Conference held in New York on February 20th ult., dealing with the connection between the spread of tuberculosis and the tenement house. This address is upon the whole an able and fair presentation of the case.

The question of successfully treating incipient consumptives in the poor is surrounded by many difficulties, but Dr. Knopf, in his advocacy of healthy dwellings for the toilers of the city, gives voice to the opinion of the entire medical profession. It is by such judicious and rational preventive measures that the scourge of consumption can be most effectually checked.

SLEEPLESSNESS.

Inability to sleep is merely a symptom, though of extremely varied origin. It may, however, be of such serious import as to require especial consideration and treatment. The first indication naturally is always to determine the cause, but this is sometimes obscure. In the failure to do so symptomatic measures may, for a time at least, be required. The subject of sleeplessness as constituting the especial complaint for which the patient seeks advice is discussed in an interesting manner by Broadbent (*Lancet*, January 27, 1900, p. 215) in a recent clinical lecture. Opiates or sedatives may be employed when the brain has been overtaxed by engrossing work, or the nervous system has been upset by a profound shock or exhausted by overwhelming anxiety or by excitement, or the habit of sleep has been interrupted by long and anxious vigils over a sick-bed.

Fresh air and exercise are among the most important influences that tend to bring the nervous system into a state favoring sound and refreshing sleep. In some persons sleep is disturbed by exceedingly slight influences, such as a change of bed, the faintest noise, the presence of light, and the like. If restlessness be present also, chloral may be employed when the pulse exhibits high tension, and paraldehyde or bromides, or morphine and hyoscyamus, when the tension of the pulse is low.

Sleep may be prevented by coldness of the feet, and relief may be afforded by hot bottles or by enveloping the parts in warm flannel. A little hot and strong beef tea or hot milk on going to bed will favor sleep when the circulation is sluggish. Sometimes vigorous local friction may be required, possibly given after making the patient stand in cold water. Sleeplessness may, on the other hand, be due to a sense of heat and burning in the feet, the patient being awakened rather than prevented from going to sleep. There may be actual objective heat, as well as the subjective sensation. The condition is sometimes associated with gout, rheumatism, or deforming arthritis, or other local disorder to which treatment should be directed.

Defective elimination of the products of proteid metabolism may cause high arterial tension and sleeplessness, and the indication then is to regulate the diet and stimulate excretion. Mercurials and salines, and drugs of this class, are useful in this connection. Low arterial tension also may interfere with sleep in the recumbent posture, although the patient may be unduly drowsy in the erect position. Tonic treatment will then be required.

Indigestion in its various forms is considered a most common cause of sleeplessness, and flatulence, especially gaseous distention of the stomach, is looked upon as one of the most active factors. In addition to treatment of the fundamental conditions, a glass of hot water at bed-time may be effectual in preventing interference with sleep. Should this not be sufficient, it may be preceded by aromatic spirit of ammonia and sodium carbonate, or an alkaline carminative draught may be given. Sodium carbonate or sulpho-carbolate with aromatic spirit of ammonia, compound tincture of cardamom, or ether and peppermint water or camphor water, and sometimes sodium bromide or ammonium bromide, may be added with advantage for a time. Friction over the abdomen or between the shoulders may aid in dissipating flatulence. This treatment should, however, not be persisted in longer than necessary. When tea or coffee gives rise to sleeplessness, its use should of course be abandoned.

For the sleeplessness accompanying or following influenza, opium or morphine with hyoscyamus or atropine may be required, should tonics such as arsenic, phosphorus, strychnine, and quinine fail to bring relief. Sleeplessness due to alcoholic excess requires, in addition to withdrawal of the stimulant, the administration of strychnine or nux vomica in considerable doses.

The Crotte Method of Treating Tuberculosis.—It was announced some time ago that this method was on trial in the wards of St. Luke's Hospital, and some curiosity was felt as to the result. The system was faithfuly tried for a period of three months, and was found to be of no value whatever. M. Crotte's attempts to exploit his tuberculosis "cure" in this country have not met with an unqualified success among the physicians of New York or the members of the American Medical Association. This field in the United States has been already somewhat overworked by native—or we might rather say, resident—talent.

News of the Week.

For the Improvement of the Milk Supply.—At a meeting of the Keystone Veterinary Medical Society, held at Philadelphia on March 20th, a discussion of questions relating to the milk supply was held. Dr. C. J. Marshall read a paper entitled "Certified Milk." He made a plea for a system of milk inspection that would provide for bacteriological examination of the milk, veterinary inspection of the cattle, and medical supervision of the attendants at regular intervals. Dr. F. A. Packard presented a communication detailing "The Plans of the Philadelphia Pediatric Society with Reference to the Milk Supply." This society has appointed a commission of five to select a bacteriologist, a veterinarian, and a physician for the purpose of thoroughly inspecting milk and noting all of the conditions under which it is obtained. Any farmer or producer of milk who permits monthly inspection of his product is to be furnished with a certificate if the milk comes up to a standard fixed by the society. Such milk should command a better price than the ordinary product. Dr. M. P. Ravenel read a paper entitled "The Part of the Bacteriologist in the Production of Pure Milk." He advocated the use of tuberculin in herds in which tuberculosis is suspected. Dr. Robert Meade Smith read a paper entitled "The Pasteurization of Milk," Dr. George S. Woodward one on "Practical Bacteriology on the Farm," and Mr. Walter R. Cuthbert one on "The Improvement of the Milk Supply of Philadelphia."

Erratum.—In the issue of this paper of December 23, 1899, was published an article in which charges were made by the writer against the so-styled Keeley cure for alcoholism, which statements we have since found to be untrue.

For the Suppression of Rabies.—Ninety-two sheep in the flock of a farmer near Erie, Pa., have been found by the State veterinarian to be suffering from rabies, and have been condemned to death. Fifteen of the animals had been bitten by a rabid dog.

A Commendable Movement.—It is stated that efforts are being made by the borough overseers of Sunbury, Pa., toward purchasing a poor-farm for the maintenance of dependents. It is hoped that within ten years the venture will pay for itself and become self-sustaining, and eventually prove a means of lowering the tax rate.

Pathological Society of Philadelphia.—At a stated meeting held March 22d, Dr. J. A. Scott presented specimens from a case of hemorrhagic pancreatitis. The symptoms so closely simulated those of intestinal obstruction that abdominal section was performed, and the patient died in the course of the operation. In addition to the lesions of the pancreas, multiple fat necrosis of the mesentery and the omentum was found. Dr. Scott presented also specimens of sarcoma of the anterior mediastinum. This had caused effusion into the right pleural cavity and was associated with metastatic neoplasms at the angle of the jaw and in the neck and the axilla. Drs. W. S. Wadsworth and W. G. Spiller presented a specimen of sinus thrombosis. The layers of the falx cerebri had become separated, and the superior longitudinal sinus, which was partly occupied by a clot, was consequently greatly enlarged. Further, a communication had been established with the straight sinus, in which a globular thrombus had formed. Drs. Wadsworth and Spiller presented also specimens of hemorrhage into the pons Varolii. Dr. Spiller presented a slide exhibiting malarial parasites in the central nervous system. The organisms of the æstivo-autumnal variety were present in extraordinary number. Bacilli and cocci also were found, but these were attributed to post-mortem infection. Dr. J. F. Schamberg presented a communication on "Tuberculosis of the Skin of the Hand from Accidental Inoculation." A nodular tumor was removed from the thumb of a laryngologist, who had probably become infected in the treatment of cases of laryngeal tuberculosis, but suffered no especial annoyance. Examination of the tissue failed to disclose the presence of tubercle bacilli, but inoculation of guinea-pigs therewith resulted in the development of tuberculosis. Drs. Joseph Sailer and M. P. Ravenel presented a specimen of aneurism in a chicken. The formation, which involved the subclavian and the axillary artery, was of considerable size, and was believed to be of traumatic origin. It was not a true, but a false aneurism. Dr. J. H. Jobson presented a communication entitled "Hernia of the Vermiform Appendix," relating a case in which such a condition was found. Dr. F. A. Packard presented a specimen of malignant disease of the rectum, with copious metastasis to the liver.

Smallpox is more than ordinarily prevalent throughout the South and West, due to neglect of vaccination, and the different local health officers are anxious and busy accordingly. In no disease do proper precautionary measures more effectually pay than the one in question. The anti-vaccination cranks have had their day, and in the face of the object-lessons before the public in the localities mentioned the time has arrived for the enforcement of the other side of the argument, and the sooner it is done the better.

Vital Statistics of Philadelphia.—The prevalence of influenza and respiratory diseases is responsible for an increase in the death rate. There were reported to the Philadelphia bureau of health for the week ending March 24th, 637 deaths—57 more than for the preceding week, and 106 more than for the corresponding week of last year, and 131 more than for the corresponding week of the year before. The largest number of deaths were due to the following causes: Pneumonia, 111 (congestion of the lungs, 12); pulmonary tuberculosis, 7; diseases of the heart, 41; convulsions, 27; apoplexy, 26; old age, 22; diphtheria, 21. Eleven deaths were attributed to influenza.

Pure-Food Congress.—The *New York Produce Review* of March 21st, reviewing the recent congress held in Washington, comments on pure-food legislation as follows: "The Brosius bill, which received the sanction of the congress, is weak in its executive provisions, which offer every opportunity for inaction and practical evasion of its proposed objects; also in relieving dealers of responsibility for selling fraudulent goods under certain specified conditions, which are very likely to result in the same methods as are now practised by the oleomargarin men, who guarantee retailers of their goods from loss by legal prosecution. Another bill introduced in the House of Representatives by Mr. Babcock to serve the same purpose as the Brosius bill overcomes these defects, and, with two or three slight amendments, would seem to provide far more efficient legislation in this direction."

The Canadian Medical Association.—The next annual meeting of this association will be held on September 12th–14th at Ottawa. The address in surgery will be delivered by Mr. Edmund Owen, of London. The president is Dr. R. W. Powell, of Ottawa, and the secretary Dr. F. N. G. Starr, biological department, Queens Park, Toronto.

The Tri-State Medical Society of Iowa, Illinois, and Missouri will meet in annual session at St. Louis on April 3d and 4th, under the presidency of Dr. O. Beverly Campbell, of St. Joseph, Mo. The secretary is Dr. J. C. Murphy, of St. Louis. The meetings will be held at the Planters' Hotel, which is also the headquarters of the society.

A New Well at Nauheim.—Dr. Schott, of Nauheim, writes us that an artesian well has been sunk there, an abundance of water being struck at a depth of about six hundred and seventy feet. The water is strongly saline and highly carbonated. The temperature is at present 89° F., but it is thought it will rise to about 95°, as that is the temperature of the water at the bottom of the boring. By this enterprise Nauheim has now obtained an ample supply of its curative resources.

The Plague is reported to be practically at an end in Honolulu, only one case having been found since March 3d. In San Francisco three Chinamen are said to have died of the disease, but there is no longer any alarm. Many inspectors, both lay and medical, have been appointed, and Chinatown is inspected daily. In Bengal the disease is on the increase, 4,725 deaths having occurred there during the week ending March 21st, 744 of these having been in Calcutta. The number of cases of plague at Sydney, N. S. W., is reported to have reached thirty-six on Monday last. There have been thirteen deaths from the disease. Eight thousand persons have submitted themselves to preventive inoculations.

Prize for a Paper on the Tropical Army Ration.—To Captain E. L. Munson, assistant surgeon United States army, has been awarded the prize offered by Dr. L. L. Seaman through the Military Service Institution for the best thesis on "The Ideal Ration for an Army in the Tropics." The value of the prize is $100.

Smallpox Throughout the Country.—According to a despatch to the New York *Times* from Chicago, a tabulated list of smallpox cases throughout the various States shows an increase for the week ending March 23d of 1,272. The figures for the week ending March 16th, in thirty-six States and Territories, show 3,952 cases, as against 5,224 for the succeeding week. The State showing the largest number of cases is Louisiana, with 2,015 cases. California is the least affected, having only three cases. New York has eleven cases.

A Trap for Sportive Physicians.—A correspondent requests us to warn the physicians of this city against two men, whose plan is to call at a doctor's office to make an appointment for a well-known jockey who is said to have been recommended to the victim for treatment of a severe disease. Just as they are leaving, one of the jockey's alleged friends says, as if on sudden thought, that there is to be a horse race that day which is a pretty sure thing from inside information, and they will help the physician place a little money—$5 or $10. They can arrange for no more, as it is hard to place it so late. The race proves to be one of money rather than horses, and the innocent but would-be sporty doctor's $10 bill goes so fast it is out of sight in a second.

Ptomain Poisoning.—About one hundred persons were poisoned by chicken salad recently at an entertainment given by a church missionary society at Lima, Ohio.

A Suit for Fees that Might Have Been.—A physician in this city recently brought suit against a builder for the loss of fees for prospective medical services. He was spattered with mortar while passing a building in course of construction. His coat and trousers were ruined, and he claimed that he lost a patient and a $15 fee owing to the time lost in drying his clothes by the boiler of the hoisting engine. The judge refused to allow his claims for contingent fees, but gave him a judgment for the assessed value of the ruined garments.

New State Hospital Districts.—A bill providing for the division of the two State hospital districts in this city into five has been approved by the judiciary committee of the State senate. The Long Island State Hospital district is divided into two, the Kings Park and the Flatbush. The Manhattan Hospital district is divided into three parts. The part located on Ward's Island, known as the men's department, shall be known as "Manhattan State Hospital East," the part located on Ward's Island, known as the "Women's State Hospital West," the part located at Central Islip as "Manhattan State Hospital at Central Islip."

Contagious Diseases in School and College.—There seems to be an unusual prevalence of infectious diseases in various educational establishments throughout the country at the present time. At Yale students are ill with smallpox and measles; at Columbia, in this city, a case of smallpox was recently discovered; one of the students at the Lawrenceville School, N. J., was recently taken with diphtheria and was removed to a Trenton hospital for treatment; several cases of measles have occurred among the students at the Naval Academy at Annapolis; the board of education has closed the public school in Bellmore Village, L. I., because many of the children were suffering from measles; and the Phillips Academy at Andover, N.

H., has been closed on account of the prevalence of measles and diphtheria among the boys.

Epidemics of Rabies are reported in the southern part of Richmond Borough in this city, where many dogs and horses have been bitten, and some, which have showed symptoms of rabies, shot; and also in the upper part of Hunterdon County, N. J., where a number of dogs, cattle, and swine have been bitten.

Regulation of Medical Practice in Italy.—The latest phase of the agitation in Italy against foreign medical practitioners is the approval by the government of a bill now before the chamber of deputies, in which it is forbidden to any one not possessing Italian qualifications to practise anywhere in the peninsula. To this there are two exceptions: The law is not effective against a foreigner who may be summoned in consultation in any special case, or who is in attendance upon a family or individual travelling or temporarily resident in the country. The second exemption is in favor of those who confine their practice strictly to foreign visitors, with, however, the fatal proviso that these practitioners are citizens of countries which accord the same privileges to Italian physicians.

Where Red Tape Worked Well.—The English papers tell a funny story of how one of the younger civilian surgeons, now serving as special consulting-surgeon to the army in South Africa, received his appointment. He was anxious to go to the war, and so one of the older surgeons already appointed made application for permission to take him as assistant at a nominal salary. This request perturbed greatly the fossils at the War Office, who could find no precedent for appointing an assistant to a civilian consulting-surgeon, and so they refused. But they didn't want to offend the important man who had asked the favor, and they accordingly appointed the would-be assistant at a nominal salary a full-fledged consulting-surgeon on a salary of $25,000 a year. Mysterious indeed are the workings of the official cerebrum.

Changes at St. Luke's Hospital.—The Rev. Dr. George S. Baker, pastor and superintendent of St. Luke's Hospital, has resigned his charge and has been appointed by the board of trustees pastor emeritus. Dr. Baker has been superintendent of the hospital for twenty-two years, having succeeded Dr. Muhlenberg, the founder of the institution, upon the latter's death. The cause of the retirement is stated to be ill-health and the need of rest. Dr. Baker was an indefatigable worker during his incumbency of nearly a quarter of a century, and the hospital owes not a little of its present prosperity to his labors. Mrs. Quintard, the directress of nurses in the hospital, resigned recently to take charge of a hospital in Cuba. The interne staff of the hospital has been enlarged by the appointment of a resident pathologist.

The American Medico-Psychological Association.—The date of meeting of this society has been again postponed, and announcement is now made that it will be held at Richmond, Va., on May 22d, 23d, 24th, and 25th. The change is made because the leading hotel in Richmond has been engaged for the week of May 7th to 12th.

The University of Hamburg.—A movement is on foot for the establishment of a new university in Hamburg. The medical department would enjoy exceptional facilities in connection with the great hospital at Eppendorf.

"The University Medical Magazine."—The control of this journal has been acquired by the board of trustees of the University of Pennsylvania, and from now on, beginning with the March issue, the magazine will be the organ of the medical department of the university, of the recently organized University of Pennsylvania Medical Society, and of the William Pepper Laboratory of Clinical Medicine. A new cover, bearing the seal of the university, has been adopted, and a board of editors has been selected by the trustees to conduct the journal.

The Mosquito Question.—In the course of a lecture recently delivered at a meeting of the Colonial Institute in London, Dr. Manson described two experiments which are to be carried out with the view of proving the practicability of preventing malaria in intensely malarial localities, and of demonstrating in an easily understood and irrefutable manner the fact that the mosquito carries malaria. For the first experiment a hut would be built in a specially malarious part of the Roman Campagna. This hut would be provided with screen doors and windows, and every precaution would be taken to maintain it mosquito-proof. Four men would sleep there this summer from May to October, and if they escaped, it would show that man could easily be protected from malaria. In the second experiment a number of virgin mosquitos (that is, insects which had been raised from the egg in the laboratory, so that they could never have got the malarial plasmodium from plants or water or earth) would be caused to sting men suffering from benign tertian fever. They would then be transported to London and be made to bite men who had never had malaria or been outside of England. If these men acquired malaria and the plasmodium could be found in their blood, this would be proof positive of the possibility of the transmission of the disease through the instrumentality of mosquitos. Of course the experiments would be conducted with the knowledge and consent of the subjects, and, the disease being benign tertian fever, there would be no danger whatever.

The Alumnæ of the New York Post-Graduate Training-School for Nurses will hold an Easter fair at their club house, 143 East Thirty-fifth Street, on March 30th and 31st, afternoon and evening. The object of this fair is to aid in the support of the club-house, which has been established only about a year, and is still something of an experiment. The club-house furnishes a home and registry for the members of the Post-Graduate Alumnæ Association, and is also a meeting-place where lectures are delivered and where business and social gatherings can occur.

Navy Department, Bureau of Medicine and Surgery, March 24, 1900.—Changes in the medical corps of the United States navy for the week ending March 24, 1900. March 16th.—Surgeon J. D. Gatewood detached from the *Lancaster* and ordered to the Bureau of Medicine and Surgery, Navy Department. March 19th.—Pharmacist F. Wood retired from active service, March 20, 1900. March 23d.—Assistant Surgeon E. Thompson detached from the *Celtic* and ordered to the *Nashville*. Assistant Surgeon M. K. Johnson detached from the *Nashville* and ordered to the *Celtic*. Assistant Surgeon H. H. Haas detached from the *Baltimore* and ordered to the *Don Juan de Austria*. Assistant Surgeon W. B. Grove detached from the *Brooklyn* and ordered to the *Scindia*. Assistant Surgeon F. L. Benton detached from the naval hospital, Yokohama, Japan, and ordered to the naval hospital, Cavite, P. I. Assistant Surgeon J. S. Taylor ordered to the *New Orleans*.

The Late Dr. Hans Rudolph Hoffmann.—At a special meeting of the North Hudson County Medical Society, held at West Hoboken, N. J., March 19, 1900, the following preamble and resolutions were unanimously adopted:

"*Whereas*, In this early history of our society, we are called upon to record the death of Hans Rudolph Hoffmann, M.D., one of our prominent, honored, and useful members. As an expression of our sentiment in the loss which we have sustained, be it

"*Resolved*, That we, the North Hudson County Medical Society, deeply regret the death of our esteemed colleague, and desire to express the sense of the great loss suffered not only by the community but by the medical profession; and be it also

"*Resolved*, That we tender to his bereaved family our heartfelt sympathy in the great loss they have sustained; and be it further

"*Resolved*, That a copy of these resolutions be sent by the society to the family, and be published in the daily papers and medical journals."

Committee, RICHARD JAHR, M.D.; A. J. WALSCHEID, M.D.; WILLIAM MENGER, M.D.

The Late Dr. John Cargill Shaw.—The New York Neurological Society records with sorrow the death of Dr. John Cargill Shaw, one of its members and its third president, serving for the two years 1878–1880. Dr. Shaw was of English stock and came to this country at the age of seventeen years. Following his graduation from the College of Physicians and Surgeons in 1874, he served in the Long Island and St. Mary's hospitals of Brooklyn, and for four years he filled the office of superintendent of the Flatbush Asylum with signal honor, and here laid the foundation of his profound knowledge of psychiatry. As president of the New York Neurological Society he was an indefatigable worker, and his untiring energy was of great service in the early days of the society. His many professional duties of late years forced upon him a less prominent position in the affairs of this body, but his literary work has made him known at home and abroad. We desire to record our appreciation of his talents and his never-failing co-operation in the interests of neurology and psychiatry. SMITH ELY JELLIFFE, LANDON CARTER GRAY, B. ONUF, committee.

Obituary Notes.—DR. AMY S. BARTON died at Philadelphia on March 19th, at the age of fifty-nine years. She was a graduate of the Woman's Medical College in 1874, and has for some time been professor of ophthalmology in the same institution.

DR. ROBERT M. GIRVIN died at Philadelphia on March 17th, at the age of sixty-five years. He was gradated from Jefferson Medical College in 1862 and became a surgeon in the United States army. He was obstetrician to the Philadelphia Hospital from 1865 to 1876, and was one of the founders of the Presbyterian Hospital, of whose medical board he was president at the time of his death.

DR. WILLIAM YANDELL, of El Paso, Tex., killed himself on March 24th. He had been in ill health for several years, and recently had become much worse and was very despondent. He was a graduate of the Gross Medical College, Denver, in 1868, and was State quarantine officer at El Paso at the time of his death.

DR. HENRY B. CARPENTER died suddenly at his home in Rochester, N. Y., on March 23d. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1890.

DR. I. S. BIGELOW died at his home in Buncombe, Iowa, on March 21st, of pneumonia. He was born at North Washington, Pa., in July, 1819, and had practised medicine for sixty years.

DR. WILLIAM WELSH VIBBERT died from heart disease at his home in this city on March 26th. He was twenty-seven years old. Dr. Vibbert was a graduate in arts of Trinity College and in medicine of the College of Physicians and Surgeons in this city in the class of 1898.

DR. DANIEL J. BUCKLEY, of Kingston, N. Y., died at the State Hospital at Middletown on March 27th. He was forty-two years old.

Progress of Medical Science.

Journal of the Amer. Medical Ass'n, March 24, 1900.

Mental Fatigue.—Edward Thorndike sums up his conclusions as follows: Mental work is not a simple matter of mental energy, of quantity of positive or inhibitory nervous discharges, but of their direction as well; mental fatigue is not like physical fatigue and requires different treatment; its warning signs are more complicated, less efficacious, and therefore more often neglected; the warnings that we do have are not measures of the degree of inability, but indefinite and at present ill-understood signs of danger; the degree of mental inability does not vary proportionately to the amount of work done without sufficient rest, but increases much less quickly up to a certain amount of mental work, and then may increase much faster, so that one straw of mental work may then break the camel's back.

What are the Most Efficient and Practical Means for Limiting the Prevalence and Fatality of Pulmonary Tuberculosis.—N. S. Davis says we must continue to take care of the infected sputum and cattle, and provide as good sanatoriums as possible for those already tuberculous; but our success for the future will depend mainly on the efficiency of our efforts to restore and maintain in their full vigor the natural conditions and processes of vital resistance to toxic agents possessed by the living human body.

The Frequency of Rickets in Infancy in Boston and Vicinity.—John Lovett Morse, from an examination of four hundred children under two years of age, considers it is a justifiable conclusion that eighty per cent. of the children under two years old, of the poorer classes of Boston and the adjacent cities, have rickets. The cause in Boston and vicinity is to be found in improper hygienic surroundings rather than in race or diet.

Thyroid Feeding in Obesity.—A. W. Sherman says that during the past four years he has used thyroid extract in a number of cases to reduce obesity with results satisfactory to both himself and his patients. He believes that in properly selected cases it is of great value, and in ordinary cases, if thyroid tablets are used occasionally after regular treatment has been stopped, the weight can be kept down almost indefinitely.

Prevention of Tuberculosis.—Homer M. Thomas considers in detail the different ways in which tuberculosis may be spread, and says that the most fertile source of infection is from the sputum, which, when dried, finds an entrance into the body. This being the case, all patients should be taught to destroy the sputum before it passes from their control.

Shoulder-Humero-Scapula Articulation.—Thomas H. Manley discusses some of the complications and sequelæ attending or following reducible or irreducible dislocations, with a brief review of the various modern operative measures now employed for their treatment.

Philadelphia Medical Journal, March 24, 1900.

Case of Cæsarean Section.—George G. Hopkins and Earle E. Woolworth report a case of Cæsarean section performed on a woman who had had one living child and four still-born children. The operation was resorted to because of the parents' desire for a living child. The woman recovered, but the writers neglect to say whether the child was alive or dead when extracted.

A Preliminary Report on the Etiology of Scarlatina.—R. H. B. Gradwohl reports the results of a bacteriological examination in seven cases of scarlet fever. These results confirm those of Class, whose work (published in the Medical Record, vol. lvi., pp. 330 and 513), the writer says, inspired him to undertake the investigation.

The Etiology and Pathology of Major Epilepsy.—William House regards the paroxysms of idiopathic epilepsy as due probably to an increase of cerebrospinal fluid, this being perhaps due to lymphatic spasm or to disturbance of equilibrium between lymphatic and general circulatory activity.

Reflex Neuroses from Phimosis.—J. Orton Edie reports two cases of insanity, one of emaciation and pallor, one of retention of urine, and one of paroxysms of apnœa, all of which were relieved after circumcision, an elongated foreskin being present in each instance.

Clinical Memoranda on Chronic Suppurative Otitis Media.—John F. Oaks, in a clinical lecture on this subject, says that the indications are to promote asepsis, insure drainage, and remove the etiological factor of the chronicity.

A Medico-Legal Case in Alaska.—Henry B. Fitts reports a case in which a woman was accused of having injected a corrosive poison into a child's gullet with a glass urethral syringe. The woman was acquitted.

A Case of Addison's Disease with Autopsy.—William Fitch Cheney reports a case of this disease in a man thirty-seven years old. At autopsy both adrenals were found enlarged and cheesy.

Radiograph of a Bullet Seen through Osseous Tissue in the Femoral Trochlea, Two Lines from the Surface of the Bone.—Charles Verge pictures this case.

Parotitis Complicating Croupous Pneumonia.—James Ely Talley reports an instance of this rare complication occurring in a woman seventy-six years old.

New York Medical Journal, March 24, 1900.

Gout and Rheumatism; their Etiology and Dietetic Treatment.—W. H. Porter attributes both of these affections to sub-oxidation due to the prolonged intake of a larger amount of nutritive pabulum than can be perfectly oxidized; also to the action of bacteria on the intestinal proteid contents. Dietetic treatment should consist in reducing the ingesta to a point where the amount taken can be perfectly oxidized. The diet should be free from an excess of the saccharine elements and all substances tending to excite putrefactive fermentation. The best results are obtained with plain diet largely composed of animal food.

What Precautions shall we Take to Avoid Leaving Foreign Bodies in the Abdomen after Operations?—H. A. Kelly gives histories of one or two cases which have come under his notice, and formulates the rules which govern his operations with reference to the avoidance of such accidents. For keeping track of the number of gauze pads and sponges used during an operation he has devised a wire frame, an illustration of which is given.

Eructation, Regurgitation, and Rumination.—H. W. Lincoln suggests, for the first, suggestion with possibly a small dose of bromide; for the second, compelling the patient to swallow back the food as fast as regurgitated, proper diet, ice pellets, bromides, and electricity; for the third, the use of foods which remain in the stomach as short a time as possible, a bitter at meals, avoidance of contraction of the abdominal muscles, internal faradization, and alkalies or hydrochloric acid, as suits the needs of the individual case.

A Case of Acetanilid Poisoning.—O. R. Summers had as his patient a woman, aged twenty-six years, who had taken only eight grains of the drug. The symptoms were those of collapse with strong convulsive movements, partial loss of consciousness, and great retching. After prolonged administration of whiskey, nitrate of strychnine, and, for two hours, artificial respiration, the patient recovered.

Cerebral Complications Caused by Extension from the Accessory Cavities of the Nose.—R. H. Craig finds a tendency to these complications from congenital defective formation in the bony walls of the nares, partial or complete closure of the normal apertures of these cavities, and pronounced virulence of the infectious material. Illustrative clinical histories of several cases are given.

The Administration of General Anæsthetics.—C. A. Temple describes the various combinations which have come into use during recent years, and names the various emergencies which may arise, together with the means of meeting them.

The Treatment of Retro-Displacements of the Uterus.—I. L. Watkins gives a general description of this condition, and enumerates the various plans of treatment which have been proposed for its relief.

Boston Medical and Surgical Journal, March 22, 1900.

Clinical Cases.—C. B. Porter reports the following: Sarcoma of tonsil, which was successfully removed by operation.—Slipping patella: An incision was made on the inside, and an elliptical piece of internal lateral patellar ligament one-half inch wide removed. The joint was not opened. The patient was discharged well fourteen days after operation.—Cysts of both ovaries, hydatidiform mole: abdominal section, removal of cysts, incision of uterus, removal of tumor; curetting; wound of uterus was closed with animal-tendon sutures. Good recovery.—Dislocation of internal semilunar cartilage: Removal. Distention of the joint with fluid that was proved to be sterile, caused a rise in temperature and in the white blood count on the sixth day after operation. Good recovery.—Ununited fracture of olecranon: Fragments were wired, arm put up on straight anterior splint reaching from finger tips to axilla, a large pad at the elbow holding the arm slightly flexed. Good recovery.—Floating cartilages in both knee joints: Incision was made on inside of left knee through capsule. Twenty-five pea-sized, hard, irregular, slippery bodies were removed.—Fracture of right patella: Curved incision made over the joint, which was found to be filled with blood clots. The joint was washed, and the fragments were wired. Recovery.—Comminuted fracture of humerus: Bone comminuted into four fragments. Operation resulted successfully, with no shortening.—Fracture of surgical neck of humerus, with displacement of head of humerus: Open section with wiring of fragments was performed. Excellent results followed.

Intermittent Gastric Hypersecretion.—Arthur W. Elting, in the treatment of this rather rare affection, uses the stomach tube and lavage with weak alkaline solutions or 1:1,000 silver-nitrate solution. Morphine hypodermically or cocaine internally is indicated when the pain is very severe. Constant tonic treatment of the nervous system is indicated during the intervals between attacks. Strychnine, nux vomica, quinine, phosphide of zinc, arsenic, etc., are indicated. Over-indulgence of all kinds and psychical excitation are to be avoided, and a carefully arranged diet is insisted upon.

Clinical Cases.—J. C. Mumford reports the following: Acute general peritonitis: The condition, due to appendicitis, was cured by operation and washing of pelvis and abdominal cavity with six gallons of hot sterilized salt solution. Good recovery.—Chopart's amputation, with tendon implantation and tenotomy: A slight limp remained, but the stump was painless.

Traumatic Rupture of Echinococcus Cyst of Liver.—C. A. Porter reports a case, relieved by operation. Incision of the right rectus muscle was followed by escape of three quarts of bloody fluid.

X-Ray Plates of Traumatic Separation of Epiphysis.—Charles L. Scudder showed tracings, and advocated open treatment of closed fractures and epiphyseal separation.

Strangulated Diaphragmatic Hernia.—S. J. Mixter reports a case. Operation was performed, but the patient died of shock.

Medical News, March 24, 1900.

Neurological Observations in the Hawaiian Islands.—Daniel R. Brower, in speaking of leprosy, says that the physicians in the islands who are experts on the subject have abandoned the hereditary etiology and regard it as contagious. They account for its rapid spread among the natives by their lowered resistance, a consequence of the great prevalence of syphilis, and their socialistic tendencies. They eat out of a common vessel and smoke each other's pipes. Climate has considerable influence over the progression of the disease. Prophylaxis is the great problem, difficult to meet on account of the long incubation period and insidious onset. Zambico believes that progressive muscular atrophy, Raynaud's disease, Morvan's disease, and syringomyelia are simply modified forms of leprosy.

A Case of Transverse Presentation; Double Uterus.—A. H. Hayden reports this case. The patient was a woman aged forty years, multipara, ninth pregnancy. She had been in labor thirty-six hours when the writer first saw her. He delivered her of a dead child. She died on the tenth day, evidently from exhaustion, as there was no other factor to account for her failure to recover.

The Thrush Fungus as a Cause of Gastritis.—W. A. Bastedo cites a case of this kind in a woman aged twenty-six years. Lavage was resorted to, which on the fourth day showed no fungus, and the patient improved from that time.

The Lancet, March 17, 1900.

Some Remarks upon External Urethrotomy.—R. Harrison describes a case, and adds that he believes the operation to be applicable, (1) in resilient and rapidly contractile strictures in the deep urethra; (2) in cases in which the wound made by an internal urethrotome is out of proportion to the natural drainage possibilities of the urethra; (3) in stricture complicated with urinary fistulæ and sinuses; (4) in cases of stricture with extravasation; (5) in some rare cases of stricture in which operative treatment is rapidly followed by acute symptoms of impending death. He would attach importance to the use of a guide, the utility of the internal operation as immediately preliminary to the external, and the more efficient provision for urine and wound drainage.

The Surgery of the Stomach.—In this lecture, A. Mayo Robson discusses perforation, gastric fistulæ, perigastritis and adhesions, hour-glass contraction, dilatation, and congenital stenosis of the pylorus, giving various statistical tables of the several operations which have been devised for the conditions above enumerated. Hour-glass contraction he regards as more common than is usually believed. He has seen one case in which the normal viscus was divided into three distinct compartments.

A Loose Foreign Body in a Hydrocele Sac.—J. R. Benson found in the sac a small, hard mass of fatty tissue which he thinks may have been a detached piece of an appendix epiploica, or may have arisen from a clot of fibrin from a previous tapping.

Unusual Ending of a Case of Empyema.—In this case of an Arab child of three years under the care of J. Cropper, the empyema of the right chest opened either into the stomach or duodenum. In spite of operation, death resulted on the sixth day.

Medical Examination of Personal-Injury Claims.—A. Benthall gives an account of his experience in the line of claim adjuster for accident insurance, and mentions certain principles of ethical and medico-legal importance.

Medical Press and Circular, March 7 and 14, 1900.

The Causes and Treatment of Movable Kidney.—Mansell Moullin draws a distinction between movable and floating kidney. The theory that the kidney is a fixed organ is incorrect. The normal range of movement is from 3 to 5 cm. The failure of the kidney to reascend on tranquil expiration, the patient standing erect and first driving the kidney down by forced inspiration, is a fair test. The anatomical relations are considered at some length. The choice of treatment lies between the application of an abdominal belt and nephrorrhaphy. Only in the milder cases does the former succeed, and then it must be combined with massage and exercises to strengthen the abdominal muscles. A belt cannot press the kidney back into place or retain it on deep inspiration in the erect posture. Pads are useless. Nephrorrhaphy never fails when properly carried out, if the symptoms have not already lasted so long as to produce an indelible impression upon the nervous system.

The Surgical Treatment of Tuberculous Kidney.—König says two different conditions must be distinguished: isolated foci in the gland substance, and the pyelitic form. Very different symptoms are presented. The so-called hæmatogenous form is difficult of diagnosis, and can but rarely be controlled. Tuberculous pyelitis can always be diagnosticated. The only possible operation is extirpation. There are no certain means of diagnosing whether the second kidney is healthy. According to Tuffier, we may operate when the other kidney is diseased, and simultaneous disease of the bladder, testicle, or prostate is not a contraindication. The author has operated eighteen times with eleven recoveries. In many cases operation prolongs life.

The Dilatations and Deviations of the Œsophagus.—John Knott concludes his article, taking up the third or hernial class of Rokitansky's arrangement. He calls special attention to Hoffmann's method for œsophageal dilatation. Gastrotomy should be performed some time before excision of the œsophageal sac, so that the patient can be fed into good condition, œsophageal rest obtained, and inflammation allowed to subside, permitting the sac to be washed out before the second operation is attempted. The writer looks upon this as the most hopeful procedure in dealing with all dilatations and diverticula of the œsophagus.

Ovarian Tumor of an Unusual Character.—T. Jason Wood records an operation upon a large universally adherent cyst with foci containing fetid green pus. The wall gave way in places. There was no trace of a pedicle. The end of the alembroth gauze packing was brought out of the wound. This was removed in forty-eight hours and a tube substituted. Good recovery followed. The absence of pedicle was accounted for by the ovary becoming detached and undergoing cystic change.

Some Surgical Cases Illustrated by Radiographs.—Noble Smith illustrates the value of the *x*-rays in a case of old Pott's fracture, in which the weight of the body was transmitted so as to impinge upon the edge of the astragalus. Immediate relief was given by cutting through the fibula, dividing the tendo Achillis, and securing better position. In a child supposed to have bowed leg, a fracture of the tibia was shown. In congenital dislocation of the hip, aid has been given; also in dislocation of cervical vertebræ.

British Medical Journal, March 17, 1900.

The Treatment of Rheumatism, with Special Reference to Prophylaxis and to Cardiac Complications.—William Ewart states that lesions of the joints are easily recognized, but not always the early beginnings of the cardiac lesions, which may develop murmurs only at a late stage. Cardiac lesions may accompany every form of arthritis down to febris rheumatica sine arthritide (Hawthorne), but their frequency and their degree are not proportionate to the degree of the joint affection nor to the intensity of the rheumatic attack. The writer then speaks of the treatment by vesication and serotherapy. It may be possible that prophylaxis may demand in predisposed subjects the application of blisters for the threatenings of an attack.

The Practical Applications of Largin in Diseases of the Eye.—Sydney Stephenson says that the application of largin, even when concentrated, is painless; if prolonged beyond a few weeks, it may stain the conjunctiva. It acts well in blepharo-conjunctivitis and in some cases of dacryocystitis. It is an efficient substitute for silver nitrate in any of the conjunctival inflammations associated with the Koch-Weeks bacillus.

Some Cases of Belladonna Poisoning.—George Scott reports the cases of three lads who took some "horse" medicine, and afterward exhibited all the signs of belladonna poisoning. He administered emetics and purgatives. To one of them, whose pulse was very weak, he gave a mixture of ammonium carbonate and spiritus chloroformi. They all recovered.

Remarks on the Holmgren Wool Test: is it Adequate for the Detection of Color Blindness?—Thomas H. Bickerton declares that the Holmgren wool test is by no means a certain discoverer of the lesser forms of color blindness. To insure certain detection of all color defects, a quantitative test for color is required in addition.

Detachment of Corneal Epithelium (?).—J. Acworth Menzies reports such a case of five years' standing, caused by a blow. He scraped the part with a sharp spoon, removing the epithelium for some little distance around the affected area, and recovery was complete.

Foreign Body in the Male Urethra.—Arthur Hawley withdrew a hatpin from a male urethra by means of a pair of curling tongs, all other methods having failed. This proved successful.

Wiener klin. Wochenschrift, Feb. 22 and March 1, 1900.

Suture of the Bladder in Suprapubic Lithotomy.—Georg Lotheissen declares that the time for recovery is considerably shortened by this method. Bierstein found this to be in the open treatment thirty-one days; with suture, from eleven to thirteen days. There seems no greater danger on the whole than in sectio alta. Angerer always employs the suture and has never lost a patient directly through the operation. In recent literature many cases are reported with excellent results. The author finds, in one hundred and thirty-seven cases, ninety-six healed primarily without fistula, *i.e.*, seventy per cent., which is even not so favorable as some others report.

A Rare Form of Aneurism of the Descending Thoracic Aorta.—Maximilian Weinberger and Arthur Weiss present this case of saccular aneurism, in which there was erosion of the upper dorsal vertebræ and the fourth and fifth ribs, with a growing together of the aneurismal sac with the upper lobe of the right lung, and the rupture of the latter into a bronchial tube. There was aspiration of blood in the right middle lobe, with chronic endarteritis of the ascending and descending aorta and ectasy of the first, eccentric hypertrophy of the left ventricle, and fatty degeneration of the myocardium. Fatty heart and fatty infiltration of the liver were found.

Alimentary Glycosuria.—Emil Raimann states that this condition does not depend on a local disturbance, but on the lowered capacity of the body to assimilate dextrose. The continued constitutional lowering of the assimilation limit is like a sign of degeneration in a chemical sense. Since by means of simple experiment on individuals a quantitative expression of glycosuria can be made, it will be possible from a mass of material to formulate the laws which cause the predisposition to this affection.

Therapeutic Studies on Sanatogen.—Eduard Rybiczka mentions as advantages of sanatogen the high nutritive value of the preparation, easy assimilation, non-irritating qualities, indifferent taste; its happy influence on the appetite in different kinds of illness, on nervous troubles, viz., sleeplessness in neurasthenics; its influence on the body weight and in some cases on the hæmoglobin; and the increase of subjective good health in patients, resulting from its use.

Berliner klinische Wochenschrift, No. 10, March 5, 1900.

Acute Non-Purulent Encephalitis.—H. Oppenheim treated a boy aged seventeen years, who suffered from cerebral symptoms following an old chronic otitis media. High fever supervened with stupor and a slow pulse. Later there appeared cortical epileptic attacks and right facio-brachial monoparesis with complete motor aphasia. The patient finally recovered as to life, but six months after subsidence of acute symptoms still had slight paresis of the right side of the mouth, weakness in the right hand, and complete motor aphasia. A diagnosis was made of acute hemorrhagic non-purulent encephalitis of the left frontal lobe, more particularly of the third left frontal convolution, including the base of the central convolution.

Nephritis without Albuminuria in Young Children.—Cassel has recently seen a series of such cases, all being under two and a half years of age. Of the nine children, the anasarca followed varicella twice, and digestive disturbances five times. In one no cause could be assigned, and in one it preceded an attack of measles, which did not, however, alter the course of the renal symptoms. In all scarlatina could be positively excluded. Most careful uranalysis failed to discover at any time the slightest trace of albumin or cell elements. Reference is made to similar cases previously reported.

Münchener medicinische Wochenschrift, March 13, 1900.

Contribution upon the Management of Infants Prematurely Born.—O. Rommel says that more than one-third of all children who die in Munich in the first months of life do so because of lack of vitality from premature birth. A series of observations upon artificial means of nourishment and supplying the requisite warmth are given, with tables showing the curve of increased weight.

A Strange Accident.—Dr. Peters saw a boy one year after he had fallen, a piece of wood of lead-pencil size having penetrated the eye, causing loss of sight upon this side, and momentary cerebral symptoms. Upon examination and incision a previously undiscovered splinter of considerable size was found penetrating the orbit.

Oxycamphor.—Hans Neumayer describes this new preparation (see MEDICAL RECORD, vol. lvii., p. 515) with tests upon the respiration and pulse in health, giving tabulated results. He finds it a trustworthy remedy in many cases of dyspnœa. The dose of gtt. xl. of oxaphor (1 gm. of oxycamphor) is recommended with considerable water given on a fasting stomach.

Œdematous Sclerema Neonatorum in Connection with Extensive Bleeding from the Lungs.—Joseph Esser relates the interesting post-mortem appearances in a twin whose sister showed no abnormality. Death had occurred on the eighth day. The lungs were hemorrhagic, and the pathology is considered at length.

A Unique Splinter Injury.—Conrad Rammstedt relates a peculiar accident by which a splinter of wood was driven in beneath the orbit, fixing the jaws by being forced against the coronoid process when attempts were made to open the mouth.

Distortion of the Ankle Joint.—Heinrich Krapf directs attention to a peculiar form of injury, which may also have as a result a painful condition caused by lateral movements of the foot. A typical case is related.

Vratch, February 19, 1900.

Endothelial Neoplasms of the Gastro-Enteric Tract.—L. V. Soboleff reports the case of a woman, twenty-eight years old, who had complained for about a year of constipation, eructations, and pain at the pit of the stomach, and for three months of vomiting and loss of appetite. For a month before coming under observation she had œdema of the face and feet. He father, she said, had died of cancer. In the region of the pylorus was felt a hard tumor with uneven surface, connected apparently with a smooth, hard, easily movable body deep down in the right hypochondrium. A dense band extended downward from this body into the right iliac fossa. The urine was turbid and contained hyaline casts, many pus cells, and a few red blood corpuscles. A diagnosis was made of cancer of the stomach with extension to the right kidney and ascending colon, and inflammation of the bladder and renal pelvis. Treatment proved of no avail, and the patient died. At autopsy a new growth was found involving the stomach, duodenum, and large intestine; other findings were fibrinous peritonitis, acute cystitis, beginning right hydronephrosis, acute pyelitis in the left kidney, diphtheritic ileocolitis, and brown atrophy of the liver and heart. The gastro-intestinal new growth was a multiple interfascicular medullary endothelioma.

Phototherapy.—I. I. Makaveeff reports seven cases treated by means of light. He used an incandescent light of 50-candle power, with a current of 100 volts, thrown on the part by means of a parabolic reflector. The séances lasted from five minutes to half an hour in different cases, but usually from ten to fifteen minutes. The patient's eyes were protected by shades or dark glasses. The cases in which this method was employed were: Lupus, 1; rheumatic joint affections, 2; tuberculous arthritis of the elbow, 1; hysterical neuralgia, 1; intense pains accompanying recurrent inoperable cancer of the left breast, 1; traumatic orchitis and epididymitis, 1. The results in every case were most encouraging.

Schleich's Method of Local Anæsthesia.—A. I. Osloff reports nineteen cases in which he employed the Schleich method of local anæsthesia with entire satisfaction. The operations were of all sorts—Pirogoff's disarticulation of the foot, removal of the thyroid, removal of a lipoma of the shoulder, resection of the rib, gastro-enterostomy for cancer, castration for tuberculous disease, etc. In order to reduce to a minimum the pain of the first prick of the needle, the writer makes a primary injection with an ordinary hypodermic syringe, and employs the larger (10 gm.) syringe later. Osloff says that the influence of suggestion in most of these cases can hardly be denied.

Operative Treatment of Congenital Enuresis.—S. K. Mayer relates the case of a twelve-year-old girl who suffered since birth from incontinence of urine. Examination showed, with otherwise normal external genitals, a widely open urethral orifice. The urine was normal in character, but the bladder was constantly empty. The urethra was narrowed by operation, and the bladder soon became tolerant of water so that the child was not forced to empty it more than once an hour or hour and a half. Three weeks after operation there was perfect control over micturition, and the child slept every night from ten o'clock to seven without wetting the bed.

Consumption in the Russian Army.—N. K. Shchepotieff presents the statistics of pulmonary disease for the Russian army from 1890 to 1897 inclusive, and discusses its causes and the means for its prevention.

La Riforma Medica, March 2 to 9, 1900.

The Vagus in Relation to Malignant Forms and Complications of Measles.—Emilio Cioffi believes that the suffocating catarrh, pulmonary collapse, cough and pseudo-croup, vomiting, diarrhœa, nausea, and sense of satiety, kidney symptoms, anuria, oliguria, œdema with or without albuminuria, otitis, and meningeal inflammation, all met with in some cases of measles, are due to the effect of the specific toxins upon the pneumogastric nerve. He has reached these conclusions through laboratory experimentation.

Dermoid Cysts of the Anterior Fontanelle.—Emilio Curzio reports a case of this rare affection, which is congenital, but becomes visible a few months after birth. Removal is the only treatment, and is best performed when the fontanelle is diminished in size, when the child is about a year old.

Lesions of the Central Nervous System in Poisoning from Sodium Salicylate.—G. Paoli says that these lesions are easily cured upon removal of the cause.

Urinary Toxicity.—Umberto Baccarani holds that there is no relation between the elimination of sulphuric ethers and indican and the toxicity of the urine.

French Journals.

The Histological Diagnosis of Rabies.—A. Van Gehuchten and C. Nelis present the results of their experimental studies, which they look upon as important and which lead them to believe that in the future one will not have to search for an intervertebral ganglion. They find that the nodular ganglion of the pneumogastric presents the most deeply seated lesions. This is readily found in the upper cervical region against the base of the skull. Here we must look for the histological diagnosis. —*La Presse Médicale*, March 7, 1900.

Pruritus, its Complications and Treatment.—Dr. Du Castel, after reviewing the various forms, points out that there are many persons affected with more or less generalized symptoms, who are really only pruriginous subjects, badly cared for at the beginning. He calls attention to two internal remedies: lactic acid and beer yeast. The former may be given to children, beginning with gtt. vi., gradually increased to 2 gm. Good results have been reported from yeast.—*Le Bulletin Médical*, March 10, 1900.

Hysterical Neurasthenic Tympanites.—Henry Bernard finds that neurasthenia, the same as hysteria, provokes intestinal spasm manifest clinically by a simple colic. The treatment is general, attacking the nerve element, and local, but generally without effect, the tympanites disappearing spontaneously. Antispasmodics, especially opium and belladonna, may be employed, but purgatives should not be given.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, March 11, 1900.

Hereditary Tic Douloureux of the Face Cured by the Continued Current of Electricity.—S. Dubois is led by the statement of Gilles de la Tourette, that no case of cure of true tic douloureux of the face is known, to relate one case as cured and mention two others apparently cured by the continuous current. In one man, now seventy-seven years of age, there has been no recurrence in twenty-six years.—*Bulletin Général de Thérapeutique*, March 8, 1900.

Congenital Ranula.—Xavier Delore gives with illustration the history of an enormous branchial cyst of the floor of the mouth. The distinction is not always easy between sublingual ranula and dermoid cyst. Among the signs in favor of the latter was that of probable adhesion to the hyoid. Treatment consists in complete extirpation of the membrane; that is, of all epithelium.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, March 8, 1900.

Specific for Bacterial Diseases of Man and Animals.—Dr. Gaube believes that in a multiple salt discovered by him, the iodobenzoyliodide of magnesium, he presents to medicine the most powerful arm it has ever known in the defence of man. His remedy has always shown activity, often curative, principally in diphtheria, though tried in rheumatism, erysipelas, typhoid fever, pneumonia, etc.—*La Médecine Moderne*, March 7, 1900.

Opotherapy.—A. Vaquez follows the historic stages of organotherapy from antiquity through the Middle Ages, and into the renaissance of a few years ago. He finds that the ancients were right in believing, and the moderns in demonstrating, that organic secretions contain an infinite number of substances of remedial value.—*La Presse Médicale*, March 10, 1900.

Some Phenomena of Excitation and Mental Depression in Relation with the Attack in Epilepsy.—Maurice de Fleury relates a number of personal observations with comments from advance sheets of his work on "Clinical Researches in Epilepsy and its Treatment," which will shortly appear.—*Le Progrès Médical*, March 10, 1900.

Hypertrophic Length of the Tongue.—C. Girod gives with illustration notes of an enormously elongated tongue in a woman, which so seriously interfered with talking that one would at first examination take her for an idiot.—*Gazette des Hôpitaux*, March 3, 1900.

Archives of Pediatrics, March, 1900.

Analytical Study of the Clinical Phenomena Observed in One Hundred and Twelve Consecutive Cases of Chorea.—John Lindsay Steven gives a statistical report of these cases. Of 87 out-patient cases, 23 were males, 64 females; 43 were between the ages of six and ten years; 60 patients had one attack, 1 had six attacks; 7 had an attack of one month's duration and under; 1 had an attack of twelve months' duration. The etiology seems to be fittingly classed under the heading "emotional" in many cases. History of antecedent rheumatism was given in 26 cases. As to condition of the urine, there seems in chorea, on the whole, little tendency to derangement of the renal function. The author likewise tabulates 25 cases observed in the wards.

Dilatation of the Colon.—F. T. Stewart and Alfred Hand, Jr., report a case of congenital dilatation of the colon in a boy six years old. The child was fed from birth on condensed milk (1 : 5), with a few breast-feedings daily. The distention was noticed first when the child was three months old. There was no clew to the origin of the affection. Treatment consisted of massage of the abdomen with olive oil, the application of the galvanic current to the abdominal muscles, and the hypodermic injection of strychnine, gr. $\frac{1}{60}$, once daily in the abdominal wall along the line of the colon. Later they were given in the arm with quite as good results. The child, however, died, and the post-mortem showed a hypertrophic dilatation of the colon and rectum.

Two Cases of Idiopathic Hæmaturia.—T. J. Elterich, after reporting these cases, states that in the treatment of this trouble rest in bed is essential. Mineral and vegetable astringents, efficient in other hemorrhagic conditions, are said to have no effect in these cases, but they may be tried.

Jour. of Laryngology, Rhinology, and Otol., March, 1900.

Antiseptic Purification of the Meatus and Adjacent Parts both for Operations and as a Treatment in Chronic Middle-Ear Suppuration.—Urban Pritchard advocates the application of a more rigid antisepsis to the classes of cases named in the title. His plan consists essentially in flushing the meatus, scrubbing the auricle, packing the canal with antiseptic gauze, and covering the whole ear with an antiseptic pad, all this being done previous to operation. When the patient is under the anæsthetic, the whole dressing is removed, and when it is finished a fresh pad is applied. With these precautions, Pritchard finds that granulations and purulent discharges are avoided and that wounds heal up much more quickly. This purification treatment is adapted to those cases in which the membrana tympani is intact and there is no suppuration. Here its use renders the surfaces of the meatus aseptic and so allows the surgeon to operate on growths in the walls or to open into the tympanic cavity without infecting the deeper parts. The plan is also of service when suppuration exists with perforation of the membrane, whether we have simply chronic otorrhœa or polypi, granulations or necrosis requiring curetting.

Two Cases of Very Extensive Unilateral Angio-Elephantiasis.—Wolff reports the cases of this nature which have appeared in literature, and gives personal experience with those referred to in the title. One patient died, the autopsy showing thrombo-phlebitis of the right femoral vein with multiple embolism of the right lung.

The Laryngoscope, March, 1900.

Report of a Case Illustrating the Importance and Possibilities in the Early Recognition and Treatment of Malignant Growths of the Larynx.—The case is reported by W. K. Simpson, who by means of drawings gives a very clear presentation of its interesting features. The patient was a man, aged forty-four years, who has been under observation for the last three years and a half. Three points are brought out by the case: (1) That all laryngeal new growths in the adult, especially those of a recurring nature, should always be regarded with suspicion, the relation between benignity and malignancy being often so close that the line of demarcation is difficult to define. (2) The difficulty attending a positive diagnosis in very early cases, during an apparent period of transition, when the microscopical examination admits of some doubt. (3) The satisfactory results which may sometimes follow a thorough removal of the growth and destruction of the underlying tissues. In some cases of early recognition and removal, even when a diagnosis of malignancy has been substantiated, a cure may be effected without resorting to laryngectomy.

A Case of Fatal Sphenoidal Suppuration.—The patient was a man aged thirty-one years, under the care of S. Lodge, Jr. For six months he had constant pain in the right side of the face and in the ear. For two months the face was swollen and there was a continual discharge of matter (often bloody) from the right naris. Examination showed symptoms of pus absorption, and a sequestrum could be made out in the region of the cribriform plate. Syphilis of nine years' standing was present. Death from brain sepsis resulted in about three weeks. Autopsy showed that to the right of the sella turcica there was some necrosis of the walls of the sphenoidal sinus. There was a large free opening from the latter into the nose, while a probe passed freely from the base of the skull through the sinus into the nose.

The Silver Salts in the Treatment of Chronic Suppuration of the Middle Ear.—E. B. Gleason commends especially the use of protargol. In his cases of prolonged otorrhœa a hypodermic syringe full of a five-per-cent. solution was injected by means of a Blake's cannula as high up into the attic as possible. The parts then were massaged with Siegle's pneumatic speculum, in order, if possible, to force a portion of the solution into more distant parts than could be reached with the syringe. The ear finally was carefully dried by means of absorbent cotton. Before using the protargol the middle ear had been cleansed with the aid of Blake's cannula and dried in the usual manner.

Archives de Neurologie, February and March, 1900.

Psychical Disturbances in Degenerative Chorea.—P. Ladame says that while many patients suffering from Huntington's chorea threaten suicide, none of them really attempts it, the threat being merely a phase of a fit of anger, resulting from the nervous excitability of these patients. Hallucinations, delirium, and symptoms of paranoia are merely accidental phenomena in this disease, but irritability and a progressive weakening of the intellect are characteristic of hereditary chorea. Complete dementia may ensue, the clinical picture being absolutely similar to that of general paralysis, from which, however, a careful examination of symptoms will suffice to distinguish it.

Hysterical Polyuria and Pollakiuria.—Jean Abadie concludes that among urinary disorders due to hysteria there is an urgent pollakiuria with or without polyuria. This may be the only manifestation of an hysterically irritable bladder. Polyuria, simple and urgent pollakiuria may all be provoked by direct hypnotic suggestion, and possess the same characteristics as the spontaneous forms. Both varieties may be cured by direct or indirect suggestion.

The Sensibility of the Blind.—The popular impression that the blind possess a more acute sensibility for tactile impressions is not supported by the numerous and carefully made observations of Professor Greisbach, of Basle. The tips of the fingers of those who see are more sensitive than those of the blind. There is no difference between them in regard to the senses of smell and hearing. Those who can see can work longer and to better effect than the blind.—*Lancet.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ARMY AND NAVY IN PARLIAMENT—GENERAL MEDICAL COUNCIL—THE WAR AND INSANITY—LORD PEEL AND THE DRINK QUESTION—PERFORATED NASAL SEPTUM—SCOLIOSIS—FALMOUTH—LEICESTER—UNIVERSITY—ILLUSTRATED JOURNAL—DR. OSLER—DEATHS OF DRS. MARCET, SCATTERGOOD, WHISTLER, AND GUY—MIDWIVES BILL AGAIN IN PARLIAMENT—A DIVORCE CASE—SOCIETIES—ENLARGED PROSTATE—COXA VARA—PATHOLOGICAL SOCIETY'S DEMONSTRATIONS—MORTALITY RETURNS—THE LATE DR. MASON.

LONDON, March 9, 1900.

IN Parliament ameliorations have been promised to the naval medical service. The numbers of inspectors and deputy-inspectors-general of hospitals and fleets are to be increased; the instruction at Haslar Hospital is to be extended and prizes awarded; study leave is to be granted; a professor of tropical diseases appointed; surgical instruments are to be supplied to all ships.

The estimates for the Royal Army Medical Corps are considerably increased, but it is by no means clear that the establishment is sufficiently provided for. Every available officer has been sent to South Africa, and numerous civil surgeons have been engaged for duties at home stations. It seems rather too previous for the minister to talk of great increase when he cannot find candidates to compete. Redress of grievances will have to be granted and the oppression by the War Office made to cease.

The General Medical Council seems to emulate the War Office in blundering. Perhaps I ought to say the law officers of the council. They have just lost another action, being ignominiously beaten by the notorious Alabone, who since he was removed from the Register has been practising. He was summoned for describing himself as M.D. Bellevue Coll., and M.D. Phil., U. S. A., and the lawyers of the council knew nothing about the bogus diplomas, but admitted them to be reputable documents of New York and Philadelphia. So the magistrate dismissed the case. These are the lawyers who muddled the case of Dr. Hunter.

Dr. Clouston, superintendent of the Edinburgh Royal Asylum for the Insane, has presented his annual report to the managers. As usual it is an interesting document. The proportion of cases due to alcohol is stated as 25.25 per cent., which is exactly the same as for the last five years. Influenza is also said to be responsible for many cases—more, in fact, than the excitement consequent on the war. But in regard to the last it is certainly too early to form any opinion, especially from the experience of one institution. Dr. Clouston thinks the selfish character observable to-day may be a reason for the little insanity attributable to the war. This seems a notion without any evidence in its favor, and in fact in direct opposition to the magnificent outpouring of help for the sufferers which has been shown in all directions and in every possible form.

The Times has published, as it has done for a number of years, the annual drink bill of the nation, the figures being, as usual, supplied by Rev. Dr. Dawson Burns. In 1899 there was an increased expenditure on intoxicants of no less than £6,169,455 above the amount of the previous year. The aggregate expenditure of the year was £162,163,474. This, Dr. Burns calculates, is equal to £3 19*s.* 11½*d.* per head, or for each family of five persons £19 19*s.* 9½*d.* Some people have begun to argue that the figures prove the prosperity of the country, but there is a darker side to be remembered. The royal commission sitting while this bill was being run up concluded that the "gigantic evil" called for a remedy, as it had become a "national degradation." These phrases were employed in the report indorsed by those engaged in the trade—the majority report, for, as you probably know, the royal commission resulted in two reports being made. The minority report was drawn up by Lord Peel, whose judicious impartiality as president of the commission had been extolled by the trade up to the last moment, but ever since his proposals he has been denounced by their organs in the press. Last week his lordship broke his long silence in a speech at Cambridge, when he asked the public "to judge between the two methods of solving the drink question" put forth in the two reports, and warned those who fancied they could take the good points of both as a basis for legislation that the differences were "vital," and if not very careful "they would fall into a trap." He said, too, "he gloried in belonging to the minority on the commission," for its report had "taken hold of the public conscience and intelligence." He added that "some extreme measures ought to be tried to make the trade subordinate to the public interests," and this object is "not only enjoined by Christianity and morality," but "enforced by the merest, lowest utilitarian principles of social and domestic expediency."

Such expressions from the man who was selected to preside over the commission on account of the conspicuous impartiality and ability with which he had filled the speaker's chair in the House of Commons are deserving of every consideration.

Among the cases exhibited at the Clinical Society was a young woman who had been previously shown in 1897, with a perforation of the nasal septum supposed to be due to tuberculous disease. In 1896 a growth the size of a filbert had been removed from the septum. Three months later the base broke through the septum. Active local treatment was employed and three injections of tuberculin were given, to which she reacted. The growth has increased in size, but otherwise the condition has improved. Sections show giant cells and caseation; no bacilli. Painting with iodine and iodide of potassium had been employed, and later guaiacol and olive oil.

There was a case of scoliosis in an infant, aged seventeen months, probably due to rickets. Three other children, surgical cases, were shown. One, aged three years, had tuberculous disease of the knee treated by dividing the patella, free exposure of the joint, removal of the affected membrane, and swabbing with pure carbolic acid. The child can now walk, though the movement of the joint is limited. Another child, aged twelve years, had necrosis of the shaft of the humerus. The sequestrum was removed, and the arm is gaining power. The other child, aged eleven years, had osteitis and periosteitis, treated by cutting down on the tibia, elevating the periosteum, and cutting a deep groove through the epiphysis and diaphysis. The pain has gone, and the child can stand.

Dr. Buchanan's report on last year's outbreak of typhoid at Falmouth has now been issued. He is not satisfied that the water supply was contaminated, but he recommends the company to adopt certain further precautions. He seems to think there was contamination through suction into the pipes at some part. He advises the town council to consider not only the disposal of the sewage, but the state of the drains and sewage, and further to provide an infectious hospital.

The Leicester Medical Society traces its pedigree through a medical book club back for one hundred years. On the 27th ult. its centenary was celebrated by a dinner which was attended by leading practitioners from various localities, including London.

The statutes recommended by the commissioners for the reorganization of the University of London have been laid on the table of both Houses of Parliament, and if unopposed for forty days will become law.

A new medical journal, illustrated, came out in February. It takes the title of *The Physician and Surgeon*, and is a weekly review of the medical world. It is illustrated and got up well, and takes a good tone. The price is 4*d*. I hardly see how it can pay.

You have probably heard that there is a movement in Edinburgh to get Professor Osler to accept the chair of medicine in succession to the late Sir Grainger Stewart.

We are not yet quit of influenza, though its effect on the death rate is less obvious. In fact, the total number of deaths registered in London last week was three hundred and thirty-four below the average for the corresponding weeks of the last ten years. Those due solely to influenza were fifty-two, and the number is falling.

The death rate of Dublin still excites considerable apprehension. After falling to 29.1 it suddenly rose to 51. But there seems a source of fallacy about this on account of the returns from one union having been delayed so that two weeks of that district are included in one.

Dr. William Marcet, F.R.S., died on the 4th inst. in his seventy-second year. He had been in feeble health for some time and sought winter climates. He died in Egypt. He was at one time physician to the Consumption Hospital, and wrote a small work on the larynx. He had been president of the Royal Meteorological Society, a fact which will show you one of his favorite studies. He delivered the Croonian Lecture for 1897, and took for his subject the "History of Respiration of Man."

Dr. Scattergood, of Leeds, died on the 22d ult., aged seventy-four years. He was dean of the Medical School, lecturer on forensic medicine, and consulting surgeon to the Hospital for Women and Children. He had been connected with the Leeds school for more than half a century, was chairman of the building-committee of the present school, and did great service in the negotiation for union with the Yorkshire College. His portrait by Sir G. Reid, subscribed for by his colleagues and friends, is nearly finished, and will probably be placed in the medical department of the college.

Dr. William MacNeill Whistler died on the 27th ult., aged sixty-three years. As a native of Pennsylvania he studied at the university of his State, and graduated there in 1860. He entered in the medical service of the Confederates. After the civil war he came to England, took the M.R.C.S. in 1871 and the M.R.C.P. in 1876. He was elected physician to the Throat Hospital in Golden Square, and at the great disruption of its staff went with the majority of his colleagues to establish the London Throat Hospital. His chief work is lectures on "Syphilis of the Larynx —Lesions of the Secondary and Intermediate Stages." He contributed the article on "Diseases of the Nose" to Quain's "Dictionary." He was a brother of the eminent painter.

The death is also announced of Inspector-General Thomas Guy, who entered the army in 1842 and had seen service in various countries. He retired in 1872. He translated Esmarch's treatise on "First Dressing on the Battle-field." He was a brother of Dr. William A. Guy, F.R.S., the author of the "Manual of Forensic Medicine."

LONDON, March 16, 1900.

THE midwives bill is not dead—it has attained a new lease of life by a snatch vote in the House of Commons after its advocates had given up all hope and introduced a measure into the Lords. Yet within two hours after this had been done, the government business in the Commons closed, one may say collapsed unexpectedly, and the way was left clear for private members. This bill accordingly came on for second reading. Mr. T. P. O'Connor led the opposition to it with skill and energy. He urged that the measure could only aggravate the evils it pretended to remove; that it would assuredly increase malpractices of various kinds; that ignorant women would be registered, and would undoubtedly carry on illegal practice, and that *The Lancet's* voting papers gave 5,000 against the bill out of 7,250 replies.

Mr. V. Gibbs stated that the General Medical Council and the two Royal colleges were in favor of the bill. This inaccurate assertion ought to have been contradicted at once; but, of course, no member was present who could do so, and the circumstance shows the mischief these bodies have done by paltering with the question. The Council of the College of Surgeons, a month ago, protested against the avoidance of the recommendations of the General Medical Council. Eventually the bill was read a second time and referred to the standing committee on law. It can be defeated at a later stage only by the most strenuous efforts, and there is a sad amount of apathy in the profession. As many as six hundred and forty men have not been ashamed to reply to *The Lancet's* query that they are indifferent. Their names should be published, as they are too selfish to consider their brethren.

Dr. Rentoul is again taking up arms. He proposes that every fellow who disapproves of the action of the Obstetrical Society in opening a back-door to practice should resign his connection with the society unless it immediately give up its diploma traffic. This is very well as far as it goes, but how about the indifferents? Will they trouble to resign even? And will the traitors who want to bring in an inferior order of practitioners of one branch cease their efforts? A more drastic measure is required to bring them into line; nothing less than the refusal to meet in consultation any man who approves of the diploma traffic. "I dissuade every woman within my influence from consulting any one of them." When the majority of the profession adopt this treatment, the "desired effect" will follow.

The case of Crook *vs.* Crook and Horrocks illustrates a danger to which medical men are specially exposed. Lawyers and doctors both know how often women have delusions as to their own chastity, and proceed to accuse some one of improper conduct with them. Dr. Horrocks has been subjected to the accusation of adultery on a confession of Mrs. Crook, which she afterward withdrew. She seems never to have thought of such a thing until a woman who practised palmistry told her she would be divorced and cause a scandal. The husband, himself a doctor, seems to have been first to the palmist and told his wife about her. The result of this palmistry has thus been most sad. A happy marriage has been made unhappy, and a respected, eminent physician subjected to a terrible ordeal. There was no evidence against Dr. Horrocks to corroborate Mrs. Crooks, and the jury dismissed him from the suit, but they could not agree as to her conduct. It is, therefore, possible that further proceedings may be taken. Much sympathy is expressed for Dr. Horrocks, and, although his costs have to be paid by the other party, that is only taxed costs, and the other expenses must be considerable. A subscription, in testimony of the feeling in his favor, has already been begun.

At the annual meeting of the Medico-Chirurgical Society I am told—for I was not present—that the president called for cheers for the relief of Ladysmith, of which news had arrived, and the grave and reverend fellows of this very sedate society responded heartily. The committee on suspended animation was requested to continue its investigations. The climatological committee has not completed its report on the baths and climates of England, but hopes to do so this year. The retiring president, Mr. Bryant, gave his address, which, according to custom, dealt chiefly with notices of the fellows who died during the year. These deaths I have reported as they occurred. The new president, Dr. Pavy, was then duly installed, and returned thanks for the honor of being elected.

The Medical Society of London celebrated its one hundred and twenty-seventh anniversary by a dinner on the 7th inst., at which the presidents of the sister societies, or, perhaps I should say, daughter societies, of this venerable institution were present. The toast of the visitors was responded to by the director-general of the army medical department, Surgeon-General Jameson, C.B., who naturally referred to the topic which occupies us all. In the course of his speech he remarked that the results of abdominal sections in field hospitals were not very good, while many soldiers wounded in the abdomen and left quiet had recovered. He also said that it was not desirable for wounded men to be taken too early on long railway journeys, as their wounds were very apt to become septic during the transit. Another point he emphasized was that female nurses are not only useless, but a real nuisance in field hospitals. It is desirable the public should know this, as many women continue to imagine that they could be of service, and are offering to go. The male nurses, trained in the army, are the proper persons for these positions. Female nurses should be utilized only far from the front, and there is a surplus supply of them at the Cape.

At the ordinary meeting of the society held on Monday, Mr. Freyer brought forward a new method of performing perineal prostatectomy. He started by admitting that the great majority of cases of enlarged prostate only required careful, cleanly catheterism. But in some cases an operation was advisable, and in just a few necessary. His plan was put forward as much less dangerous than suprapubic cystotomy. He removed the tumor by a pararectal incision, preceded by external urethrotomy. He described his operation in detail, and related a case. In the discussion on this, the perineal distance was mentioned as too great for intravesical growths to be reached. For these it was suggested that McGill's operation was effective, though not without risk. It was asked whether the division of the hemorrhoidal nerves, necessarily involved, had led to any inconvenience. Further, it was remarked that as enlargement of the prostate took place in different directions, operative procedures must also be varied.

Coxa vara was the subject of a subsequent paper, the author of which said he had seen seven adolescent cases, five of them being demonstrated by skiagrams, the other two being too well marked to call for the *x*-rays as an aid to the diagnosis. He thought it likely other cases would be met with if looked out for.

The Pathological Society held another of its laboratory meetings on the 6th inst. On this occasion the laboratories of the conjoint colleges were lent for the meeting, and interesting demonstrations took place. Dr. Grube related some experiments he had made which seem to confirm those of Sternberg, published a short time ago, as to the probability of diabetic coma being due to B-amidobutyric acid. He had injected this into the veins of twelve cats. Coma followed with respiration such as is seen in diabetic coma, and the urine was found to contain substances met with in diabetes, besides sugar, which last is not of much significance, as that is often found in cats after other operations.

Dr. Bain described a case of typical rheumatoid arthritis, in which he analyzed the urine during seven successive days of a fixed diet. Lactic acid was not present. The only change was a diminution of uric acid and phosphates.

Dr. Cadman described experiments on the rootlets of the ninth, tenth, and eleventh cranial nerves in cats and dogs.

Drs. Brodie and Dixon demonstrated the action of some drugs on the pulmonary circulation and bronchial muscles. Suprarenal extract increased blood pressure and led to congestion of the lungs. Muscarin caused spasm of the bronchial muscles, and they said pilocarpine also did this. Atropine neutralized the effect, as they said urethan would also do, suggesting its use in asthma. Dr. Brodie demonstrated the actions of diphtheria toxin on the spleen. The first effect was constriction of the vessels. This was rapidly followed by relaxation; then by alternate relaxation and contraction; lastly by complete paralysis.

Dr. Pavy demonstrated the production of glycosuria by exalted respiration, which he had shown some years ago to be the effect. Further, jointly with Drs. Brodie and Sian, he showed the effect of phlorizin in producing the same effect as an artificially perfused kidney. It has previously been shown that injecting this drug into the renal artery of one kidney produces this effect in that organ, while its fellow remains unaffected until the drug reaches it through the circulation.

The mortality returns are more favorable. The London death rate last week fell to 18.8, the rate of the three preceding weeks having been 22.9, 21.5, and 19. For the thirty-three large towns the rates for the last four weeks have been 25.8, 24.2, 21.2, and 20.4.

Dr. Mason, of Dublin, died on Saturday, aged eighty years. This venerable gentleman had held an important position as a teacher of anatomy and of medicine for about a quarter of a century, chiefly in connection with the Ledwich school, of which he was one of the founders, but also as physician to Mercer's Hospital. I mentioned in January that his son had died. Now the father follows.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

The Occupation of Bloemfontein.—Since my last letter Bloemfontein, the capital of the Orange Free State, which was clearly the objective of Lord Roberts' march to the eastward, has been occupied by British troops. The city capitulated without resistance upon a message from the field marshal that he should commence shelling in twenty-four hours, unless the inevitable was recognized, and submission made. President Steyn fled northward, and the keys of the public offices were sent out to Lord Roberts. The occupation of Bloemfontein marks a distinct stage in the war, and all humane people must rejoice that its surrender did not follow upon any protracted siege or loss of life through stubborn fighting. There are no medical aspects from which to view the taking of the city; but, as far as the British are concerned, the bloodless victory is of good medical omen. The troops under Lord Roberts have now been engaged in six weeks' hard marching, varied with some fierce fighting. They will at length obtain a rest which will certainly save many of them from hospital treatment.

Intombi Camp contained, after the relief of Ladysmith, twenty-one hundred sick. By the second week in March a large proportion of these were convalescent, while others had been deported to more sanitary places on the lines of communication. By medical advice Ladysmith was evacuated as soon as possible after it was relieved.

The Casualties among the Royal Army Medical

Corps.—The British military medical officers have borne their share of fighting in carrying out their professional duties, and have not come unscathed out of the war. Their casualties by the beginning of March numbered four killed, three dead from disease, and fourteen wounded. Those killed in action were Major Edward W. Gray, Captain Matthew L. Hughes, and Lieutenant Hugh B. Onraet. All three were fine officers; but Captain Hughes was something more. He was one of the most promising scientific men in the service, and had already made researches into certain climatic diseases that were recognized by epidemiologists as being of great importance. Captain R. H. G. E. Holt, the fourth officer whose death is recorded, died from wounds received during his gallant behavior at the front in Sir Redvers Buller's operations at the Tugela.

The Imperial Yeomanry Hospital.—Since the inception of the scheme of this hospital by Lady Georgiana Curzon and Lady Chesham, £100,000 have been subscribed for its purposes. With this money a base hospital of five hundred and twenty beds has been equipped (I have already described the site chosen for its establishment to your readers); while a field hospital of one hundred beds has also been prepared, and a complete bearer company. Major Stonham, senior surgeon to the Westminster Hospital, who has gone to Africa as chief surgeon to the Imperial Yeomanry Hospital, has a grand but responsible billet.

The Use of Hollow-Nosed Bullets.—There is no longer any doubt that some of the Boers have used so-called explosive bullets. A large number of hollow-nosed bullets, such as are used in the pursuit of big game, have been found upon Lord Roberts' Boer prisoners, while the surgeons with the British advancing column have felt certain, from the more serious nature of the wounds, that explosives were being used. This probably means that other bullets are running short with the federal troops, for the Boer generals would not willingly risk the loss of the sympathies of Europe by the employment of weapons that are universally condemned by civilized nations. The Boers confidently assert that in using hollow-nosed bullets they are only following the example of the British, who have employed Dumdum bullets. No such bullets have been served out to the British soldiers for the campaign, and the persistency of the stories in European papers was a subject of wonder, until a Boer surgeon explained to a Dutch paper the possible origin of the mistake. It appears that many Lee-Mitford bullets, the bullets used by the British, have been manufactured at the Dumdum factory and issued to the troops in cases bearing the name of that factory. These cases have been noticed, and led to the obviously genuine belief among the Boers that the British were using explosives. The surgeon who suggests the explanation of the mistake says that he looked for the effects of explosive bullets among the Boer wounded, but had been unable to find them.

The Plight of Mafeking by the second week in March was becoming acute. Messages had reached telegraph stations both north and south of the beleaguered hamlet stating that the garrison was reduced entirely to siege soup made of horses and dogs, that the horses' provender was being made into bread, that the mortality among the natives was very high, and among the few women and children still left terrible. A relief column has started northward from Kimberley, and another has been for weeks coming southward from northern Rhodesia; but whether either will arrive in time is doubtful. The water supply of Mafeking is said to be polluted, and the medical men with the relief columns anticipate finding a large proportion of Colonel Baden-Powell's tiny force prostrate with typhoid fever and dysentery. Since the beginning of the siege two hundred and ninety-two persons have been killed and wounded or died of disease at Mafeking out of a total of less than two thousand.

Yet another Hospital Ship, the *Avoca*, is now riding at Durban. As in the case of the *Lismore Castle*, the transformation from a passenger steamer to a hospital ship was entirely carried out by Durban artificers.

ACTING ASSISTANT SURGEONS IN THE ARMY.

To the Editor of the Medical Record.

Sir: In your issue of March 17, 1900, you mention the dissatisfaction that exists among the acting assistant surgeons of the army who served in the Spanish-American war, etc. This is not a new grievance, and is not confined to those who served in the Spanish-American war and the Philippine rebellion, but it has continued to exist since the Mexican war, and no apparent effort seems to be made by the medical department of the army to remedy it, and so long as physicians can be obtained to fill this position it will probably continue to exist.

Every person who knows the position of the acting assistant surgeon of the army knows his grievance is a just one; but there it seems to end. Your suggestion that it would be better policy to place the status of these men on a satisfactory footing than to continue an out-of-date and unpopular system, ought to meet with the approval of the medical profession.

There is a bill now pending before the United States Senate, S. 1782, introduced by Senator Thomas C. Platt, which will, with a slight modification, give to the acting assistant surgeon of the United States army the same status, rank, etc., in the army as is now given to the acting assistant surgeons of the United States navy, which is that of an assistant surgeon of the United States navy.

The injustice of depriving an acting assistant surgeon of the army (who has to sacrifice home comforts and follow the army in the field and share the dangers with the troops) of salary, if he is wounded or disabled by disease contracted while in discharge of his duty, is apparent, when a government clerk in Washington or elsewhere, who is exposed to no danger and is not deprived of home comforts, is allowed one month's vacation with full pay each year.

You are quite right in your statement that an acting assistant surgeon of the army cannot receive a medal for bravery, however distinguished his services may have been. This is the ruling of the War Department.

I take this opportunity to commend the surgeon-general of the navy for his success in obtaining the proper recognition of the acting assistant surgeons of the navy in the late war, and to call the attention of the medical profession to his interest in the medical staff. I submit his letter, which will show the benefits obtained by the act approved May 4, 1898, for the acting assistant surgeon of the navy, in the late war, compared with his condition previously. It is an example that the medical department of the army might follow with advantage, and would be of benefit to the members of the medical profession who enter the service.

"53,961.

"Washington, D. C., February 9, 1900.

"Dear Sir: Referring to your letter of February 8th, I would state that the law authorizing the appointment of acting assistant surgeons in the United States navy during the War of the Rebellion is contained in the act approved July 24, 1861, and in section 1411 of the Revised Statutes, which states: 'The Secretary of the Navy may appoint for temporary service such acting assistant surgeons as the exigencies of the service may require, who shall receive the compensation of assistant surgeons.'

"The volunteer medical officers during the War of the Rebellion were not commissioned. They were appointed by the Secretary of the Navy. The law does not mention their rank; it simply refers to their compensation. They, however, wore the uniform of an assistant surgeon and received all the consideration shown to an assistant surgeon in the regular service. The act approved May 4, 1898, is the only one conferring rank on acting assistant surgeons. The acting assistant surgeons in the United States navy, who served during the War of the Rebellion, were not appointed by the President.

"Very truly yours,
"(Signed) W. K. Van Reypen,
"*Surgeon General, United States Navy.*"

On February 13, 1900, General Orders were issued from Headquarters of the Army, adjutant-general's office, with the approval of names of the Secretary of War, which contained a list of names of persons who have distinguished themselves in the Spanish-American war by "especially meritorious acts or conduct in service." Among these names are several members of the medical profession who should receive medals of honor, and it seems to me that these medical heroes deserve to be mentioned in every medical journal published in the United States. I have culled the following from the General Orders, viz.:

1898.

June 24, and July 1 to 3. Dr. John Guitéras, now out of service (then acting assistant surgeon, United States army): For gallant and meritorious conduct in attending the sick and wounded on the field of battle at Las Guasimas and Santiago.

June 24. Dr. José M. Delgado, acting assistant surgeon, United States army: For distinguished service, by being constantly on the firing line, exposing himself in the most conspicuous manner to the fire of the enemy, in the care of the wounded, in the battle of Las Guasimas, Cuba.

June 30. Dr. Maximilian Lund, then acting assistant surgeon, United States army: For especially meritorious conduct attending the sick and wounded under fire, during the reconnoissance at Tayabacoa, Cuba, and subsequently in making extraordinary efforts to secure their embarkation on the transports.

July 1. Captain Thomas R. Marshall, assistant surgeon, Forty-first infantry, U. S. V. (then acting assistant surgeon, United States army): For gallant and meritorious conduct during the battle of Santiago, Cuba, where, under fire, he cared for the sick and wounded.

Dr. Thomas Y. Aby, now out of service (then acting assistant surgeon, United States army): For gallant conduct in attending to the wounded on the battlefield and the sick in the trenches, while himself ill from fever and heat; this at the battle of Santiago, Cuba.

Dr. Harry W. Danforth, deceased (then acting assisting surgeon, United States army): For especially meritorious service rendered during the battle of Santiago, Cuba, in caring for sick and wounded. He was killed while at work at the dressing station at the "Bloody Ford," on the morning of July 2.

Dr. Francisco E. Menocal, now out of service (then acting assistant surgeon, United States army): For gallant and meritorious conduct during the battle of Santiago, Cuba, where, under fire, he cared for the sick and wounded.

July. Major Frederick J. Combe, brigade surgeon United States Volunteers (then acting assistant surgeon, United States army): For especially meritorious service during the Santiago campaign, in establishing, with the aid of others, the division hospital at the extreme front, carrying a portion of the supplies for several miles on his back during drenching rains and in deep mud.

Drs. Hamilton P. Jones and William W. Calhoun, acting assistant surgeons, United States army: For especially meritorious service during the Santiago campaign, in establishing, with the aid of others, the division hospital at the extreme front, carrying a large portion of the supplies for several miles on their backs during drenching rains and in deep mud.

Dr. G. Goodfellow, civilian and volunteer aid to General William R. Shafter: For especially meritorious services, professional and military, during the campaign in Cuba.

July and August. Dr. Nicholas Senn, now out of service (then lieutenant-colonel and chief surgeon, United States Volunteers): For his surgical work during the Cuban campaign, and for making a scientific study into the causes of typhoid fever among the troops.

August 13. Major Frank H. Titus, surgeon United States Volunteer staff (then acting assistant surgeon, United States army): For establishing a first-aid hospital in the village church, and for the manner in which he came to the front with a detachment of the hospital corps through a heavy indirect fire, and the efficient manner in which he rendered services to the wounded at the battle of Manila, Philippine Islands.

August. Colonel Charles R. Greenleaf, assistant surgeon-general, United States army: For most efficient and hazardous services in the medical department in Cuba and during the Puerto Rican campaign, especially in the yellow-fever camps.

General Lawton's last act was to recognize the bravery of Dr. E. K. Johnstone as follows:

"Army Corps, Manila, P. I. December 18, 1899. —E. K. Johnstone, acting assistant surgeon, United States Army, was attached to Kent's battery. His performance of professional duty in field and barracks had hitherto attracted the favorable attention of the officers of this command; but the exceptional daring and high sense of duty exhibited by him during this expedition, particularly at the battle of Zapote River, when he gave the immediate first aid to the wounded along the river bank and on the bridge, deserve material recognition.

"It is recommended that this gallant young surgeon be commissioned either major and brigade surgeon or major and surgeon of volunteers.

"Very respectfully,
"W. H. Lawton,
"*Major-General Commanding, First Division U. S. Volunteers.*"

The above just tribute of the War Department to the heroic deeds of the members of the medical profession who volunteered their services in the late war ought to be sufficient to receive the gratitude of a patriotic nation, and should obtain for the acting assistant surgeons of the army the recognition they deserve and what they ask for from Congress, as well as the approval of the surgeon-general of the army.

John T. Nagle, M.D.

THE MORTON-ROCKWELL DISCUSSION.

To the Editor of the Medical Record.

Sir: I would like to refer the readers of the Morton-Rockwell discussion to a quotation from Beck's Murray, "A System of Materia Medica and Pharmacy," published in 1828, vol. ii., page 240: "Electricity is applied medicinally under the form of the stream or continued discharge of the fluid, under that of the sparks, and under that of shock; the first being the most gentle, the second being more active, and the last being much more powerful than either of the others. At the introduction of electricity as a remedy, it was highly celebrated for its efficacy in a number of diseases. It is usually applied under the form of sparks; the spark is communicated, etc., from the machine while the machine is being worked. The shock is given by discharging the Leyden phial." Again from "Braithwaite's Retrospect," 1845, part xi., page 33: "The second fact is, that if the nerves of a living animal be submitted to the passage of the electric current, renewed at short intervals (static induced current), tetanic contractions are excited."

C. L. Squire.

March 24, 1900.

PURE FOODS AND DRUGS.

To the Editor of the Medical Record.

Sir: Apropos of your editorial upon the adulteration of food in your issue of March 10th, it is of further interest to note that the Senate committee upon manufactures in its recent report suggested that a board be appointed by the Department of Agriculture to have full control of the standards of foods, drinks, and drugs, and that the board use the "United States Pharmacopœia" as its guide. Thus a step has been taken to secure legislation of a national character, as suggested two years ago by the National Pure Food and Drug Congress. The object and intent of such a board would be to protect the right of the individual to obtain in foods, drinks, and drugs, exactly what he requires, not alone from the standpoint of obtaining his money's worth, but also to protect him from injuring his health. "Patent medicines," as well as drugs, would, therefore, come under the control of this board, at least to this extent: A patent medicine would have to be harmless to any individual, and could not be sold for more than its true valuation. Thus the sugar-and-water preparations, as well as the "cures" containing injurious amounts of opiates and alcohol, would no longer be allowed on the market, unless, perhaps, a true formula accompanied each package. Every well-informed physician knows that it would be better for the public to continue using pepper of which sixty per cent. is cocoanut shells, than for one individual to take a patent medicine. Who of us has not seen the ruined intestinal tract from the free use of cathartics, or does not know of the consumptive dying of cirrhosis, or the neurasthenics—yes, and maniacs—from the employment of headache cures, "pain killers," etc.?

If I am correct in my opinion that the jurisdiction of this board would extend over the control of patent medicines, would it not then be well for the various medical societies to lend their influence to the immediate passage of such a bill? I would suggest that resolutions indorsing this committee's recommendations to the Senate be forwarded to Washington immediately.

John Joseph Nutt, M.D.

San Diego, Cal.

REFORM IN THE AMBULANCE SYSTEM.

To the Editor of the Medical Record.

Sir: In an editorial upon "Needed Reforms in Our Ambulance System," of your issue of January 6th, you suggest that the ambulance service be undertaken as the closing duties of the surgeon's hospital career. A serious objection to such a change would be the impatience of the surgeon to launch himself out into the world, and his great temptation to resign his position. It is the promised reward of house-surgeonship which keeps the interne, and especially the ambulance surgeon, contented. After one month of first and second ambulance call at Bellevue Hospital the surgeon has had practically all there is to be gained from the service. After that each week—each day even—may bring to him some new experience, but he does not learn enough to repay him by any means for his long hours and hard work. There occur to me two ways in which the ambulance service might be changed to advantage. One is that the hospital surgeon should do his ambulance duty during his last six months, as you suggest, but that he should receive a salary during that time. Most of the surgeons would be glad of the opportunity to make a little money at the end of so many years of hard study and work in the colleges and hospital, and as experienced surgeons and salaried officials they would indeed reform the ambulance system. My other suggestion is that every hospital or dispensary receiving any moneys whatsoever from the city should be required to keep one or more ambulances in service and a sufficient number of beds to care for all the emergency cases they may receive. This would divide the city up into such small districts for ambulance service, that its adoption with a rule that all patients are to be brought to the hospital, would lessen to a minimum the dangers from a wrong diagnosis upon the part of the surgeon.

John Joseph Nutt, B.L., M.D.,
Late House Surgeon, Bellevue Hospital.

San Diego, Cal., March 10, 1900.

Surgical Suggestions.

Duodenal Ulcer should be treated on the lines laid down for gastric ulcer. Operation is indicated in repeated and exhaustive bleeding with symptoms of acute perforation. Perforation usually takes place in the peritoneal cavity. The symptoms are either those of generalized sepsis, suppuration, or perforation of the gall-bladder, peritonitis, etc. Differential diagnosis from ulcer of the stomach is, as a rule, impossible. Bleeding is an almost constant symptom, the blood appearing both in the stools and vomited matter. The mortality is high—there were twenty-four deaths in twenty-eight cases of perforation treated surgically.—Pagenstecher, *Deutsche Zeitschrift für Chirurgie*, Bd. 52, Hft. 5, 6.

Surgical Hints.—In phlegmonous conditions affecting the hand or forearm, long-continued baths in mild antiseptic solutions are of great usefulness. The ordinary elongated fish-boiler is very convenient for this purpose, as the whole hand and forearm may be placed in it, and allowed to remain in it for hours at a time.—In making plaster-of-Paris bandages, or in using those that are ready-made, see if the plaster appears to be damp. If so it will not set well, but may be greatly improved by placing it in the kitchen oven for a short time.—Pain occurring symmetrically about both shoulders in children should lead to examination for cervical caries. In rheumatism the pain is of a very different character, and practically never affects both sides so evenly.—In concussion of the brain death often takes place through paralysis of the respiratory centres. The prompt use of artificial respiration may tide the patient over his danger. If the heart centres appear to be involved we must stimulate, and for this purpose there is nothing better than heat applied to the precordial region, together with such drugs as nitrite of amyl, nitroglycerin, strychnine, ammonia, etc. Alcohol and strong coffee may be administered in enemata.—In partial amputations of the foot it is essential to prevent contraction of the tendo Achillis, either by tenotomy or by the use of splints, otherwise the foot is likely to point downward, which will much interfere with the fitting of an artificial limb. The tendency of surgeons is more and more to discard these partial amputations and cut above the malleoli, an operation giving less chance of sepsis, a better stump for an artificial limb, and greater facility of performance.—Always prepare packages of sterilized sponges, made out of cotton, or cotton and gauze, and always containing the same number, say six. Then if the operation is in a cavity, one will always know whether he must account for six, twelve, eighteen, etc.—*International Journal of Surgery*, December, 1899.

The Prevention of Cancer.—Cancer of the uterus is preventable. If we believe, as Emmet has conclusively proved, that cancer of the cervix almost always begins in the cicatricial tissue in the angle of a laceration, then by removing the cicatricial tissue and repairing the laceration we would put a stop to this dreadful disease, at least so far as the cervix uteri is concerned. And this is just what has happened in my own experience. I have made it a practice at the clinics and hospitals to repair every lacerated cervix that comes before me, with the result that out of five thousand gynæcological cases, of which there are complete histories, there are at present less than twenty-five of marked laceration of the cervix remaining unrepaired. The result is most striking: instead of having two or three cases a month of cancer of the uterus, as I had ten years ago, I now see only three or four in a whole year.—A. Lapthorn Smith.

The Incidence of Cancer.—Oöphorectomy, either combined with removal of carcinoma of the mamma or performed subsequently in consequence of recurrence, or undertaken as a last resort in inoperable cases, has sometimes produced remarkable amelioration of symptoms, and often total disappearance of undoubted cancerous tumors of the breast. The good effect of this operation has been attributed either to atrophy of the breast consequent upon removal of the ovaries, or to suspension of some occult influence supposed to be exercised by that upon the breast. A very serious drawback to both these theories is that they do not explain the undoubted benefit, marvellous indeed in some cases, which follows oöphorectomy when it is performed for recurrent scirrhus in the pectoral region, many months after all breast tissue has been removed in a former operation. . . . Oöphorectomy as a mode of treatment of cancer is so frequently combined with the administration of the thyroid extract that it is difficult to apportion their respective shares in any improvement that takes place.—Dr. Arthur Jackson, *British Medical Journal*, November 25th.

Methods of Suturing Wounds.—Drs. W. Watson Cheyne and F. F. Burchard ("Manual of Surgical Treatment," p. 159) give the following summary regarding the method used: When there is no tension on the edges of the wound, and a very small, fine scar is required, either buried sutures may be used with no sutures in the skin at all, or the finest horsehair may be employed. When very great tension is present, button sutures should be used, after undermining the flaps, and, in addition to them, deep relaxation sutures of silk wire should also be inserted, these being sufficiently numerous to separate the edges of the flap, which should be coapted by a fine, continuous buttonhole stitch. When there is only a moderate amount of tension, interrupted silkworm gut, reinforced by a fine, continuous coaptation stitch of silk, may be made use of; and lastly, when there is little or no tension, and stitch marks are unimportant, the edges may be appoximated by means of thick or fine silk.

Rigid Perineum.—

℞ Chloroform	℥ ij.
Ether	ʒ i.
Spt. colognien	ʒ i.

M. S. Apply locally.

Indispensable and infallible.—Southworth.

Painless Lithotrity.—Rectal and vesical injections of antipyrin lessen vesical sensibility. In a case operated upon by Guyon, crushing and evacuating the stone was painless after—

℞ Antipyrin	gr. xxiv.
Tr. opii	gtt. x.
Aquæ	℥ iij

had been injected per rectum three-quarters of an hour before the operation.—*Ann. des Mal. des Org. Génit.-Urin.*, No. 7, 1899.

Stricture.—Massage in the perineo-bulbar region for five minutes daily with—

℞ Potass. iod	4 gm.
Lanolin,	
Ung. aq. ros	āā 15 "

—Bazy.

Excoriations on Hemorrhoids.—

℞ Chrysarobin	0.08 cgm.
Iodoform	0.02 "
Ext. bellad	0.01 "
Ol. theobrom	2 gm.

For one suppository. Use two or three daily.

—Boas.

Aneurism, suggesting pulmonary tuberculosis, was detected by *x*-ray examination. Other cases showing the value of *x*-rays in suspected aneurism are given.—F. H. Williams, *Boston Medical and Surgical Journal*, January 18th.

Suppurative Teno-Synovitis may be produced in one of three ways: First, by direct septic infection of the synovial sheath by a wound. Second, by a secondary infection from adjacent structures. This is seen frequently in the finger, where an infective cellulitis spreads from the connective tissue about the vaginal sheath into its interior. An infective process in a phalanx or joint may extend in a similar manner. Third, in rare cases by a secondary process, as in pyæmia," scarlet fever, typhoid fever, etc.—W. Arbuthnot Lane.

Surgical Treatment of Fibromyomata of the Uterus.—(1) The surgical treatment of fibromyomata should consist in their removal. (2) The bilateral removal of the adnexa by laparotomy has been generally abandoned and is indicated only as a complement of ovariotomy when uterine fibromata exist which do not cause grave symptoms. (3) The removal of fibromyomata should be made through the vagina when the operation is easily made by that route. (4) Laparotomy is preferable when vaginal hysterectomy appears to present real difficulties. (5) Myomectomy and vaginal hysterectomy should be made by anterior simple hemisection of the uterus or in a V-shape. (6) Large interstitial tumors are scooped out by a cutting tube and removed by lozenge-shaped morcellation. (7) The removal of large pedunculated fibromata by laparotomy presents special indications. Abdominal myomectomy is only rarely indicated. (8) The operation of choice for large and multiple interstitial fibromata is complete abdominal hysterectomy by subperitoneal decortication of the lower segment of the uterus, with closure of the pelvic peritoneum.—E. Doyen.

Reviews and Notices.

Treatment of Diseases of the Nervous System: A Manual for Practitioners. By Joseph Collins, M.D., Professor of Nervous and Mental Diseases in the New York Post-Graduate Medical School; Visiting Physician to the New York City Hospital. Illustrated by 23 Engravings. New York: William Wood & Company. 1900.

"Books cannot always please, however good.
Minds are not ever craving for their food."

THE book which Dr. Collins has written may not please all, but many must surely be craving for the food he offers. It will be a surprise to the general practitioner that a book of six hundred pages should be written on the mere treatment of nervous diseases. There is a general impression abroad that the treatment of nervous diseases does not amount to much; that the diagnosis is the important matter; and that, if it were not for the difficulty which the average practitioner experiences in recognizing nervous diseases, the sphere of the neurologist's usefulness would be distressingly limited. The every-day experience of the specialist proves that there is indeed an art in treating nervous diseases and nervous patients, and his fellow-neurologists will be profoundly grateful to the author of the book we are reviewing for proving to the medical public that there is much to be said regarding the therapeutics of nervous diseases.

Dr. Collins has had a grateful task before him, and has acquitted himself well of it. His style, though not terse, is vigorous; his manner combative and original, and his conclusions on every subject are almost certain to be both interesting and suggestive. The author was fortunate enough not to have been hampered by tradition, and though he sets out to speak of the therapeutics mainly, it is natural that he should also have much to say about the diagnosis and the pathology of the various diseases which he has considered. No fault is to be found with him for having written a condensed general treatise on nervous diseases. He has had the special privilege, moreover, and no one could deny him the right, to say what he cared to say and to leave much unsaid that he did not choose to dilate upon. We have noted only one rather striking omission in the chapter on the treatment of cerebral apoplexy. Very properly the author considers cerebral hemorrhage and softening of the brain from embolism and thrombosis; he discusses the treatment appropriate to each condition; but, although he gives the etiology and the pathology of cerebral hemorrhage and of embolism and thrombosis, he fails to state the most important thing—namely, how the practitioner who is attending at the bedside of a patient just laid low from apoplexy can tell whether the apoplectic stroke is due to hemorrhage, embolism, or thrombosis. A table giving the symptoms of the various modes of onset of the apoplectic attack would be very helpful, and we trust that in future editions—which the book is certain to have—such a table will be inserted. In almost every other chapter of the book the information which the author gives regarding the diagnosis and pathology contains practically all that the physician who wishes to treat a patient intelligently needs to know at the time such treatment is projected, and this means much as an indorsement of the extremely practical character of the book.

The general plan of this manual is to be commended. Part I. consists of a chapter on the "Causes and Origination of Diseases of the Nervous System," and of a second chapter on the "Prevention of Diseases of the Nervous System." Both these chapters are so thoroughly characteristic of the author's manner of writing and of thinking that we trust all will become acquainted with their contents. Hereditary and congenital influences, the neuropathic diathesis, the stigmata of degeneracy, the rôle of infection, and the influence of syphilis are thoroughly discussed. The author has a tilt with those who are constantly speaking and writing of "syphilis of the nervous system" as though it were "a disease with defined anatomical foundation and unvarying morbid changes." We know of no recent writer of repute who has spoken thus loosely of syphilis of the nervous system, and we find that the author has given a very able presentation of the subject along the orthodox lines adopted by a number of his predecessors. There is no reason to disagree with him in his general discussion of this special question, except that he makes syphilis responsible for certain diseases which others of equally large experience would not ascribe to it. Only one author of any note has maintained—and his conclusions were based on insufficient evidence—that a majority of infantile cerebral palsies were due to syphilis. The statistical evidence that has been carefully collected by previous writers points to the very opposite conclusion. We can subscribe, however, to Collins' fling at the "*laisser-aller*" fashion in which antisyphilitic treatment is generally conducted. If he will stir up the syphilologists to greater efforts in this respect, he will deserve the gratitude of the medical profession and of the laity. Chapter III. contains a very useful list of the drugs employed in the treatment of nervous diseases, and stamps the author as a firm believer in medicinal agents. In maintaining this position he is evidently anxious to remain in good company; but he does not, by any means, limit his therapeutic measures to the exhibition of drugs. In the chapters on hydrotherapy, massage, and electrotherapy, as well as the one on exercise, rest, and occupation, Collins shows that he has full regard for every remedial measure calculated to benefit the patient. His remarks on hydrotherapy are thoroughly sane. They may not meet with the approval of those who consider hydriatric treatment a panacea, and his fling at "institutional" treatment may arouse some opposition; but he has unquestionably done good work by showing that great benefit can be derived from hydriatric procedures practised in the patient's home.

After devoting one hundred and forty-four pages to the consideration of the general methods of treatment, the writer enters upon a detailed consideration of the treatment of various diseases. These are discussed in practical sequence, and the order, although somewhat different from that adopted in the ordinary text-book, is such as to be hardly open to serious criticism. But we cannot quite understand why, after a chapter on the treatment of cerebral apoplexy, there should be another near the close of the book on hemiplegia. In the consideration of tabes, the author gives a detailed account of recent methods for the re-education of the ataxic extremities, with a series of serviceable illustrations, which will help the practitioner unacquainted with these methods to inaugurate them in any case that may be under his care. While the treatment of the chronic disorders of the central nervous system is considered briefly enough, a very detailed account is given of the proper manner of handling the large number of functional diseases which come under the observation of the practitioner and the specialist. It cannot be our purpose to enter into a consideration of the various forms of treatment recommended by the author, and it will suffice to state that he is entirely in line with the most modern ideas regarding the therapeutics of the nervous system. He is generally conservative enough. In his partial indorsement of cerebellar operations he has perhaps been a little less conservative than others would have been; but individual experience is bound to leave its imprint upon the work of every writer who does not merely copy from others, and so we have no fault to find with Collins' position in this matter, all the more as he is excessively careful in the general consideration of the surgery of cerebral tumors.

The general practitioner will find Dr. Collins' work all that it claims to be; and even specialists will find it a convenient book of reference, if they are anxious to determine what special methods of treatment had been advocated in any given disease. The book deserves to be widely read and carefully studied.

The Dispensatory of the United States of America. By Dr. George B. Wood and Dr. Franklin Bache. Eighteenth edition, thoroughly revised and largely rewritten, with illustrations, by H. C. Wood, M.D., LL.D., Joseph P. Remington, Ph.M., F.C.S., and Samuel P. Sadtler, Ph.D., F.C.S. Philadelphia: J. B. Lippincott Company. 1899.

THE advances made in drug study since 1833, when the first edition of this standard work was issued, are in a measure reflected in the increase in size of the volume now necessary to cover the great number of remedial agents. Aside from the accurate information concerning materia medica and the medical properties of drugs and their uses, we have, first, a glossary of terms employed; an index of diseases, giving the reference to the particular remedy mentioned; and in Part III. we find the subjects formerly embraced in the appendix, with the additions of official tests and various tables, many of which are now introduced for the first time. A feature of value is the alphabetical table of formulæ and molecular weights. The index alone takes up just one hundred of the two thousand pages. All who have had to do with the production of so important a work, representing such a vast amount of research, are subjects for congratulation.

The Cost of Living as Modified by Sanitary Science. By Ellen H. Richards, Instructor in Sanitary Chemistry in the Massachusetts Institute of Technology. New York: John Wiley & Sons. London: Chapman & Hall. 1899.

This little duodecimo of one hundred and twenty pages, without preface, starts with Chapter I. on "Standards of Living." The author then studies the service of sanitary science in increasing productive life, household expenditure, rent, operating-expenses, food, intellectual and emotional life, etc. A valuable and well-written book.

Recollections of a Rebel Surgeon (and other sketches); or, In the Doctor's Sappy Days. By F. E. Daniel, M.D. Illustrated. Austin, Tex.: Von Boeckmann, Schutze & Co.

Literary physicians keep springing up in various quarters. Southern writers (in the South) have as yet been slow in going into non-medical work. We have, however, had in this city two notable examples of Southerners who have recently made a success with the pen outside of professional writing. Dr. Daniel, of the *Texas Medical Journal*, gives in his preface an explanation of the reasons why the average Southerner speaks as incorrectly as he does. He then makes the "Old Doctor" tell some "alleged" humorous, sad, and pathetic stories, all said to be true. The literary merit is not of a high order; the illustrations are very crude, and too much slang is indulged in to make pleasant reading.

Consumption and Chronic Diseases: A Hygienic Cure at Patient's Home of Incipient and Advanced Cases. A Popular Exposition of the "Open-Air Treatment," with Latest Developments and Improvements. By Emmet Densmore, M.D. London: Swan, Sonnenschein & Co., Paternoster Square. New York: The Stillman Publishing Company, 15 Sterling Place, Borough of Brooklyn. Pp. 198.

The author contends most valiantly for the efficacy of the Nordrach treatment by fresh air and overfeeding, and cites many instances in which those living in cities who had advanced pulmonary tuberculosis have been wonderfully helped. There is undoubted truth in his contentions, although they are perhaps tinged too much with a sanguine enthusiasm, leaving the reader with the impression that failure would be exceptional. It is but another proof that the profession is relying more and more upon hygiene to combat this scourge.

Chirurgie du Foie et des Voies Biliaires. Par J. Pantaloni (Marseilles). Avec 348 figures dans le texte. Paris: Institut de Bibliographie Scientifique. 1899.

To the surgeon who wishes to have a complete and succinct history of the status of the surgery of the liver, the gall bladder and its ducts, this volume cannot fail to be of great use. The subject is taken up systematically, beginning with the simplest operative procedures and progressing to the most difficult, and there are numerous very good explanatory illustrations. The author has evidently used great care in examining the literature of his subject, and has been successful in bringing it up to date, and we are glad to note instances of credit due to American surgeons placed where it belongs—something not too common in European writings. The descriptions of operations are lucid, and the various forms of mechanical aids are well illustrated. The volume is a scholarly production and an excellent addition to any library.

International Clinics. Edited by Judson Daland, M.D., Instructor in Clinical Medicine and Lecturer on Physical Diagnosis in the University of Pennsylvania. Vol. III. Ninth series. Philadelphia: J. B. Lippincott Company. 1899.

This quarterly of clinical lectures and specially prepared articles on treatment and drugs continues to receive contributions from the best men of this and other countries. This issue contains the names, among others, of Baginsky, Bernhardt, Dieulafoy, Gärtner, Gerhardt, Goldscheider (who has an excellent article on the method of treating tabes patients), Graucher, Helferich, Krehl, and Robin, not to mention many of the best-known American names. In a work intended for practitioners, it would seem somewhat out of place to devote so much space to definitions and generalities with which every student is familiar, as has been done by the writer of the last specially prepared article.

Contribution à l'Étude des Obsessions et des Impulsions à l'Homicide et au Suicide. Par Georges Carrier. Paris: Felix Alcan. 1899.

This is one of the publications issued by the *Progrès Médical*, and deals with the tendencies to suicide and homicide in degenerates, considered from the medico-legal standpoint. It is a very readable little brochure.

Chirurgie du Rectum. Par E. Quénu et H. Hartmann. Vol. II. Paris: G. Steinheil. 1899.

The second portion of this excellent work on rectal diseases treats of the tumors of the region, adenomas, villous, fibrous, lipomatous, cancer, sarcoma, myxoma, enchondroma, lymphadenoma, dermoid cysts, and angiomata. Like the first volume, it is superbly illustrated, having seventy-four figures in the text and twenty-eight plates, many colored, as insets. The authors are to be congratulated upon so successful a presentation of their investigations and years of labor, as are the editors upon the quality of the press-work.

A Practical Treatise on Medical Diagnosis, for Students and Physicians. By John H. Musser, M.D., Professor of Clinical Medicine in the University of Pennsylvania, Physician to the Philadelphia and the Presbyterian Hospitals, Consulting Physician to the Woman's Hospital of Philadelphia and to the West Philadelphia Hospital for Women, Fellow of the College of Physicians of Philadelphia, Member of the Association of American Physicians, etc. Third edition, revised and enlarged. Illustrated with 253 woodcuts and 48 colored plates. Philadelphia and New York: Lea Brothers & Co. Pp. 1082.

The third edition of this work is a considerable improvement over its predecessors, good as they were. The chapter on nervous diseases has been entirely rewritten, while changes in the articles on the sputum and on the eye are to be specially noted. Too high commendation cannot be paid to the pictorial records of physical signs, where at one glance the disease picture is seen and grasped in a manner more like that which the clinician employs and less like that of the text-book. It is a most complete work, richly and expensively illustrated and thoroughly modern. The first section describes the data obtained by inquiry and observation, and serves to point out how to ask questions and how to see; the full description of the blood as regards diagnosis, and the symptomatology of general morbid processes. Part II. takes up in order the nose and larynx, lungs and pleuræ, heart, blood-vessels, and the mediastinum; mouth, fauces, pharynx, and œsophagus; stomach, intestines, and peritoneum; liver, spleen, and pancreas; kidneys and nervous system.

Anæmia and Some of the Diseases of the Blood-forming Organs and Ductless Glands. By Byrom Bramwell, M.D., F.R.C.P. Ed., F.R.S. Ed., Physician to the Royal Infirmary, Edinburgh; Lecturer on the Principles and Practice of Medicine and on Clinical Medicine in the School of the Royal Colleges, Edinburgh; etc. Philadelphia: P. Blakiston's Son & Co. 1899. Pp. 450.

When the author's well-known clinical ability and clearness of description are remembered, this work hardly needs an introduction. From start to finish it abounds in magnificent pen pictures, logical discussions of theories, and commonsense methods of treatment. After a short general description of what anæmia is, its causes, forms, general clinical symptoms, and microscopic characteristics, he proceeds to treat in an exhaustive manner the subject of chlorosis. The usual and unusual symptoms are all well described, and the treatment of obstinate cases by very large doses of iron is especially insisted upon. Among his many useful methods of teaching particularly to be noted is the tabulation of eighty cases with regard to the ages, number of red corpuscles, percentage of hæmoglobin, conditions of menstruation and bowels, and specially noteworthy peculiarities in each case. The next section is devoted to pernicious anæmia, treated in much the same manner, and containing all the important points in differential diagnosis. Here again he has tabulated forty-five cases with reference to age, sex, hæmoglobin, red-blood-corpuscle count, and the relative numbers of megalocytes, microcytes, and white corpuscles; the marked or moderate showing of poikilocytosis, the presence or absence of marked prostration, loss of weight, hemorrhages, dropsy, vomiting, diarrhœa, jaundice, and fever, with the characteristics of the urine. The pathological physiology of the disease is discussed most fully and in an interesting manner. It will be remembered that the arsenic treatment was introduced by the author and has since become universal. Besides the table just mentioned, a most interesting summary of forty-eight cases is added, giving a succinct history of each, its duration and treatment. Leucocythæmia's varieties, etiological factors, morbid anatomy, clinical history, diagnosis, and differential diagnosis, prognosis, and treatment occupy the next chapter, followed by a similar handling of Hodgkin's disease. Under Addison's disease he analyzes twelve cases seen by him during life, with a summary of the history, course, and treatment in each. The final chapters are devoted to myxœdema, of which disease he has seen forty cases; exophthalmic goitre, with a summary of seventy-nine cases, and acromegaly. Throughout the work the greatest completeness and clearness obtain. When one has finished reading, there seems nothing which one could desire to be added to the text, and one feels satisfied that the pictures of the various diseases have been impressed upon the mind in a manner not soon to be forgotten. The stamp of the personal observer is seen from the introduction to the index, and the author has the happy faculty of transferring that experience in a most impressive way. It is to be regretted that pictorial illustrations have not been introduced into this work, since many of the conditions mentioned are such as can best be taught in this manner. If the reader could have a picture of a myxœdematous patient, for instance, near at hand while reading the masterly descriptions, certainly it would be a great aid. Also pictures of the microscopical appearance of the blood would have added to the book's value. For every practitioner this volume would seem a necessity, both to be perused in continuous reading and to be sought as a reference in diagnosticating puzzling and atypical cases, or treating obstinate ones. The book is essentially practical without omitting the necessary theoretical discussions, such as tend to make us broader practitioners and urge us to further effort to seek the causes of disease. The theories are concisely treated, however, and could not possibly fatigue the reader if he is of average intelligence.

TREATISE ON ORTHOPEDIC SURGERY. By EDWARD H. BRADFORD, M.D., Surgeon to the Children's Hospital, etc., and ROBERT W. LOVETT, M.D., Assistant Surgeon to the Children's Hospital, etc. Illustrated with 621 Engravings. Second revised edition. New York: William Wood & Company. 1899.

THE first edition of this work, published several years ago, soon made an enviable place for itself, and for some time it was not thought necessary to publish a second. The time finally has come when such a second edition seemed desirable, and the authors have given us what is practically a new work. New subjects and illustrations have been added, and old subjects have been amplified. As is natural, diseases of the vertebral column take a large share of space, in which, among other things, we find an interesting discussion of the forcible reduction of spinal deformities. The conclusion is conservative, and we are warned that great care is necessary in the performance of the operation and in the selection of cases. There are many illustrations showing the changes in bones and joints due to chronic disease, which means practically a description of the tuberculous lesions of bones and joints, and the various forms of apparatus are illustrated and explained by photographic reproductions and diagrams. The chapter on the subject of clubfoot is excellent and complete, and is freely illustrated. There is a careful weighing of the comparative value of the various methods of treatment, and several excellent results after operation are shown by diagram. The importance of over-correction of the deformity is emphasized. The authors do not accept intra-uterine violence as the cause of the so-called congenital dislocations, but believe that such abnormalities depend upon some sort of defective nutrition and development. The hip, as it is most important in this regard, receives most attention. The deformities due to rickets and allied conditions are given considerable space, and the choice between osteoclasis and osteotomy is left to the individual operator, except that osteoclasis is not thought desirable in adults. On the whole, this book is the best work of reference upon orthopedic surgery which is now extant in this country, and must prove very satisfactory to the specialist as well as to the practitioner.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 15, 1900.

WILLIAM H. THOMSON, M.D., PRESIDENT.

THE third meeting devoted to the discussion on cancer.

Cancer of the Breast.—DR. ROBERT T. ABBE read this paper. The question whether surgeons could eradicate cancer of the breast was open to debate. Light was dawning on the subject, showing a bacterial origin, and any advances made in curing the disease he believed to be the outcome of this knowledge.

Lymphatics and Cancer.—During the past fifteen years the minute anatomy of the efferent lymphatics demonstrated that recurrences occurred along these lines, and this pointed to the only method for eradication. In early life cancer of the breast was purely a localized disease. Certain anatomical features of the lymphatics were considered: (1) Those that drained the mammary gland toward the axilla; (2) those that extended outward to the overlying skin; (3) those in the deep aspect of the gland draining to the deep cellular tissue of the pectoral muscle; (4) those that drained toward the sternum. Clinical observations would determine which series would be the most involved. The axilla received the greatest part of the infection. The progress of this disease along anatomical lines gave us such knowledge as was of interest in the effacement of this disease; infiltration of contiguous parts must be recognized.

The Operation of Removing Cancer of the breast was now practically a bloodless one, and there was no shock following. Too much emphasis could not be laid upon the fact that the infected cells should not be squeezed into the wound. The hard scrubbing of the skin by the nurse he regarded as instrumental in causing recurrences in the neighborhood of the scar; there should be less handling and friction of the skin. Infection by escaping cells was no myth.

Statistics.—To determine the actual value of the work done in this field in recent years one must be able to state the length of time the patients were rid of the disease, and what approach to eradication had been made; this could be done only by (1) the statistical method, and (2) the personal impressions of the surgeon. Halsted's statistics were the best obtainable. He gives an analysis of 133 operations done at the Johns Hopkins Hospital during the preceding nine years; forty-one per cent. of the patients lived without recurrence and without signs of metastasis; 76 patients survived more than three years; 40 lived more than three years without recurrence. Stiles, of Edinburgh, emphasized the results of microscopical examination proving the course of lymphatic absorption, namely, by the lymph channels accompanying blood-vessels. In thirty per cent. cancerous nodules were found on the posterior surface of the pectoralis major. In Dr. Abbe's personal experience, notes taken during only the past fifteen years showed 33 cases in private and 90 in hospital practice, or 123 cases altogether.

Among the 33 cases in private practice that he had recently heard from, 1 patient lived six years; 1 lived five and a half years; 1 lived four years; 2 lived three years; 5 lived two and a half years. Twenty-five per cent. reached the three-year limit, and nearly as many approached it. From a personal estimate of the modern operative work he found to-day that the impressions of men had passed the stage of pessimism and they were now high optimists. He thought that the three years' immunity was within the reach of most surgeons. Removal of the involved lymphatics gave two advantages: the pressure in the neck was not seen, and the cachexia, formerly so distressing, was now rarely present. Recent experiences showed that recurrence of cancer after operation need not discourage the patient or the operator.

Muscular Tissue, Lymphatic Glands, and Skin.—DR. J. A. FRANZ TOREK said that the question that arose as to what we should do besides removing the breast were three in number: (1) Should we remove more skin than that which covers the breast, and if so, how much? (2) Should we remove glands? (3) Should we remove muscular tissue? Since the publication of Dr. Halsted's paper he had invariably removed both pectoral muscles, and he had never had occasion to regret such a radical measure. Among the cases operated upon in this way there were a number of hard-working women, servant-girls, etc., and after removal of the pectoral muscles, while they declared that some power was lost, yet they were perfectly able to move the arms. It was pretty well agreed that the muscles should be removed. If the entire axilla, anatomically considered, were cleared out, it would be a good piece of work. In the hands of the earlier surgeons, clearing out the glands from the axilla as high up as an inch or two from the border of the pectoral muscle was supposed to be effectual; but they really never entered the axilla. As Dr. Abbe stated, in a great many cases infected glands were present behind the pectoral muscles; he had repeatedly seen them. The method of removing them by simply lifting the border of the pectoral muscle was very unsatisfactory; this fact alone gave justification for removing the pectoral muscles. This method thoroughly exposed the entire stretch of connective and fatty tissue, which contained a considerable amount of infected glands, from the outer border clear up to the clavicle. One should never forget the supra-clavicular glands. They could be more easily diagnosed before operation than any other glands; they could be palpated with great ease, which was not the case with the sub-pectoral glands; the latter could not be diagnosed unless large. The removal of the skin was of the utmost importance; it should be lavishly sacrificed. The skin was the foremost organ for recurrences. In order to be safe against recurrence we should sacrifice a considerable amount of the skin.

Results of Operation.—DR. THOMAS H. MANLEY said it appeared that cancer was more common in the breast than in any other organ of the body. Up to recent times genuine typical mammary cancer had been regarded as practically incurable. He averred that he had heard a statement made by Dr. Abbe a few years ago to the effect that relapses were so common, and fatal consequences so general from this operation, that the late Dr. Sands had become so discouraged as to practically decline to operate. The fundamental question now was whether we were assured and satisfied beyond a doubt that the lesion was of local character, and that it was not disseminated or generalized before it manifested itself in the mammary gland. It should be caught at its birth and eradicated then and there. A patient with cancer of the breast wished to know two things before operation: What was the danger to life, and whether it would impair the usefulness of the limb; also, whether the disease could be cured or not. Some cancers relapsed at once and some not for years. The new operation certainly guaranteed a non-recurrence in the breast or chest wall, for the reason that there was nothing left in which the cancer could return. Halsted's operation entailed a large sacrifice of muscle and fascia. He had seen elephantiasis result in an arm from which the lymphatics had been removed; he had seen cases in which the nerves of the arm had been injured, resulting in more or less paralysis and numbness of the limb; he had seen cases in which the patient had been left with troublesome painful sores upon the thighs, making walking impossible. He had not undertaken the wide dissection of the parts because the simple excision of the gland, in the majority of cases, had not been followed by recurrences; the average period being three years and some having passed nine years. His experience had not been similar to Dr. Abbe's in regard to the disease following the course of the lymphatics; in one instance it recurred in the larynx; in another, in the opposite mammary gland. He was hopeful that the new operation would do all that was promised for it, but he believed that it was yet in the trial stage.

DR. WILLIAM H. THOMSON said that five years ago he had a patient whose breast had been removed by Dr. Sands ten years before for cancer, and she had remained healthy until that year, when it developed in the axilla. The original operation was simply its removal, and no attempt had been made to follow it up into the axilla. The growth had remained quiet ten years before it started afresh.

Cancer of the Uterus.—DR. HENRY C. COE read this paper. He said that surgical treatment, in order to be successful, should be done in time; that was the key-note of success. Accumulated experience emphasized that one point—early diagnosis and removal. In Germany thirty per cent. of the patients were operated upon when first seen, and that was the explanation of so many radical cures. In early diagnosis lay the hope of improvement in our statistics. This implied in general the recognition of certain symptoms and the investigation of causes. An idea existed and was firmly fixed in the minds of some physicians, that a woman could not have cancer without pain, cachexia, and a foul discharge. These were symptoms of advanced disease. Uterine hemorrhage was significant of commencing carcinoma, and, in short, was the only symptom; it was slight and atypical, and so was often overlooked. It was universally believed that the approach to the menopause was the explanation of every irregular discharge of blood, and that belief was responsible for so many neglected cases. If the trouble was within the uterus, the sharp curette or palpation was the only positive means of learning the nature of the disease; some foci of disease might easily be passed over by the curette; therefore a careful history was very important. After a positive recognition of the disease the questions arose, whether it was a suitable case for operation; was it confined to the uterus or did it involve adjacent viscera? These questions could be determined only by an examination conducted under an anæsthetic. We should also determine to what extent the glands were involved. He had operated upon a case that day. Five years ago the woman was examined in a New York hospital by several surgeons, and it was supposed that the disease had invaded the peri-uterine tissues, and she was told her case was absolutely hopeless. The sharp spoon and cautery were used, and the woman lived eight years perfectly well. She was referred to him a few weeks ago, when he found that the disease had recurred and extended up the cervical canal. One man would operate when another man would not; some general rule should be laid down for our guidance. In general, operable cases should be divided into those confined to the uterus and into those in which there were limited mobility of the uterus and induration at the base of the broad ligament. The prediction as to the lease of life without operation was notoriously uncertain. It was well known that patients with inoperable cancers might enjoy life, free from pain, even three years after the death sentence had been pronounced. Dr. Jackson, who was so opposed to hysterectomy, had made a study of statistics, and stated that the duration of life was longer when the cancer was treated palliatively than when submitted to operation. Three times as many women died from cancer as from childbirth. In less than ten per cent. of operable cancers were the patients saved by operation.

Increased knowledge of the histology of cancer confirmed the opinion of the older gynæcologists that erosions or ulceration were often exciting causes; therefore it might be well to amputate the cervix or to use the sharp curette in the early stages. Regarding the question of removing the uterus by the vaginal or abdominal route, all were agreed that the abdominal route was indicated when the organ was too large to be removed by the vagina. He was sure the trend of opinion was now in favor of the abdominal method in corporeal disease. It might be contraindicated in stout patients or when rapid work was necessary. Among twelve hundred and seventy-three cases collected by thirty-eight surgeons in Europe, a mortality of 14.6 per cent. was shown. In patients that could be traced, the average period of exemption was found to be three years and four months. Even if ten per cent. of the lives could be prolonged two, five, or seven years, or even permanently saved, there was decided hope for the future. Abdominal hysterectomy for cancer of the cervix was rapidly growing in favor; it appealed to the modern surgeon as the only method by which ultimate results could be improved. Assisted by catheterization of the ureters and ligation of arteries, operators worked with a thoroughness formerly regarded as impossible. Statistics were not now obtainable, but soon would be, as data were now being prepared. The speaker closed his paper by calling attention to the importance of the early recognition of the disease; the profession and laity should be instructed as to the importance of hemorrhage as an early symptom. Every suspicious case should be submitted to rigid search, careful examination being made under anæsthesia. A thorough removal should be made; unless incision was made in healthy tissue the operation was palliative rather than curative. He believed that abdominal hysterectomy would be the method of the future.

Prognosis.—Dr. Herman J. Boldt stated that the prognosis must depend upon the early diagnosis. The reason for the difference between operable cases found in this country and those occurring elsewhere was simply that abroad, whenever there was any abrasion of the mucosa of the cervix, the scrapings from it were subjected to a careful and scientific examination by one who was competent to judge what was pathological and what was histological. The prognosis depended largely upon the seat of the disease. The gravest cases of all were those in which the cancer was present in the so-called cervical portion, especially in the vaginal tract, because here the cancer was situated beneath the endometrium. When the parametrium was involved, or the deeper tissues were encroached upon, compressing the ureters, the prognosis was exceedingly unfavorable. Certain unrecognized cases, treated in a palliative manner, when they came to the surgeon and were recognized, had gone beyond the vaginal portion proper, and had encroached upon the supra-vaginal portion and attacked the parametrium; these were also very unfavorable cases.

Diagnosis.—One could not be too careful to investigate each and every case in which there was the slightest suspicion of the disease being present. A woman between the ages of thirty and thirty-five years, who showed signs of atypical bleeding, was the one offering the most unfavorable prognosis. When such a condition was present it was not enough merely to scrape the mucosa of the uterine cavity with a curette, because the part most desired to be removed was frequently left. It was necessary to remove every vestige of mucosa and submit it for examination. In the cervical canal, when the disease started in the endometrium microscopical examination became unnecessary, because here the disease was well marked. He did not believe it was necessary to make a manual examination of the uterine canal; forcible dilatation was uncalled for; curettage would do all that was needed. In doing this an anæsthetic was absolutely necessary. In examining under an anæsthetic a point that should not be overlooked was that the vagino-abdominal examination was entirely unsatisfactory; unless one made a recto-abdominal examination the results would never be satisfactory in revealing the amount of infiltration. An examiner of large experience could determine whether the infiltration was malignant or inflammatory.

Treatment.—Regarding igni-extirpation, if it was shown that the cases operated upon were such bad ones, and that twenty per cent. of the patients recovered for a certain length of time, he thought that was a favorable showing. In one of his cases there had been no recurrence for nearly three years. The case had been declined by one of the leading surgeons of the city. Igni-extirpation was done, and although bad complications arose, in that secondary to the igni-extirpation both ureters gave way and there was a ureteral fistula on both sides, the result of the hot iron, yet the patient did well. Comparing vaginal with abdominal hysterectomy, he did not believe that the modified operation would give better results than vaginal hysterectomy if performed when the patients were in a suitable condition.

Diagnosis.—Dr. W. Evelyn Porter said that during the past eight years he had been studying cases in the various hospitals in the city, and had had the assistance of various pathologists in studying sections of uteri that had been removed; the result of his study showed the difficulty in making a satisfactory diagnosis except in the superficial forms of the disease. Hemorrhage should be considered in connection with the age of the patient. Hemorrhage occurring in women past forty years of age, in the large majority of cases, was due to malignant disease. He preferred the abdominal route in operating, and thought it would be the choice of the future.

Educate the People.—Dr. Philander A. Harris, of Paterson, N. J., believed that, in the hands of a skilful operator, the vaginal operation could surely be done without a death rate greater than five or six per cent., when the cases were judged to be operable. The profession should be educated, and secondarily the people should become educated, as to the importance of operation. Another serious obstacle to proper treatment was the erroneous impression women had about the menopause; which caused this period to be much neglected on their part. It was common for a woman who menstruated ten or fifteen days each month to say that it belonged to the change of life; she did not consult her physician. It was also common for them to disregard leucorrhœa at this period. Many cases had gone on to tissue necrosis before a physician had been consulted. As to diagnosis, if débris had been submitted to a pathologist and he reported that he could not find signs of malignant disease, that was not conclusive, and the pathologist should not be blamed for what he did not find; if he found evidences of malignant trouble, it helped the physician.

Clinical Facts.—Dr. W. Gill Wylie said there was no doubt that cancer was a disease not prone to attack normal or healthy tissue; it attacked only degenerated tissue, and was much more commonly found in such organs as the breast and uterus. Recognizing that fact, he believed much could be done, and would be done, in the removal of degenerated tissue to aid these patients. Speaking of age in prognosis, he said he had seen carcinoma occurring in persons under twenty years of age, but had never seen one cured. Between the ages of twenty and thirty years the disease was rapid and very dangerous, whether occurring in the breast or the uterus. As the woman grew older it was more manageable. After the menopause, hemorrhages might occur; if they did, it showed that the disease was more advanced. If women stopped menstruating for six months, and then began again, that pointed to cancer; if they stopped one year, and began again, it was more certainly cancer; if they stopped for two years, and then went on again, it was most certainly cancer. In regard to the results of operation, he said there was a difference between the results obtained in foreign hospitals, and those in ours, because in our institutions we had the poorer people, who, when they came in, were in a bad condition; if they entered such an institution as Bellevue, it was because they were almost helpless cases. In private practice it was different, and here the death-rate should not exceed one or two per cent. in the hands of an expert. He believed it was more difficult to get good results in operating upon the breast than upon the uterus. If the uterus was movable, he thought the vaginal operation was the quicker one. As to suppuration, he did not know whether it had the power of killing cancerous tissue or not; but, in many operations in which he thought they would fail, extensive suppurations had taken place, big abscesses had formed, and the patients had recovered and still remained well. In inoperable cases in which the radical and complete operation could not be done he used the steel—not the copper—curette, getting away the diseased tissues; then, with a knife or with scissors, he cut in every direction all diseased portions; he then applied a saturated solution of chloride of zinc; this gave better results than could be obtained by the use of the galvano-cautery.

New Instruments.

A NEW NASAL SPLINT.

By Francis W. Alter, M.D.,

TOLEDO, OHIO.

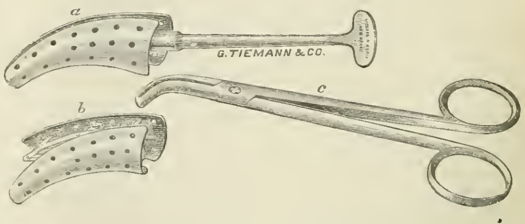
In presenting to the profession this dilating nasal splint, to be used in the after-treatment of operated deflected septums, I wish to emphasize the following favorable features of this device:

1. The drainage permitted by the outspread halves of this instrument when *in situ* is maximum, and such a thing as "clogging" never occurs, thus fostering that much-desired element, good drainage. Besides, the breathing through the previously stenosed nostril is at once established, and the satisfactory effect to the patient, as well as the surgeon, is immediately in evidence.

2. In the removal of the splint for the daily cleansing-process, a few turns of the key converts the splint from size *b* to *a*, as indicated in the cut, and its removal and subsequent introduction are effected without the usual pain accompanying this manœuvre with the splints now generally used.

3. The distal as well as the proximal end of the splint dilates equably. This is of the utmost importance, especially when the deflection is situated somewhat posteriorly.

4. Drainage being good, irrigation, with the splint in position and proper precaution as to the forward position of the head, instructions not to swallow during the injection of the fluid, and by imparting a moderate velocity to the inflowing medicament, can be successfully carried out. There is no need of its daily removal, and I leave the splint in position for five days, replacing it again for a like period, and removing it entirely at the end of that time. If, in its first introduction, too much or too little dilatation of the splint has been effected, a few turns of the key either way will bring about the desired effect. The daily removal of the splint carries with it certain ill effects, and the argument against the daily removal of the dressings on a broken limb also holds good here.



5. In my experience the material of these splints, metal instead of rubber, offers less opportunity for sepsis. In four cases in which I have used this splint, I had no rise of temperature, yet the opposite was of regular occurrence with the vulcanized rubber tubes.

These splints are made by George Tiemann & Co., of New York, and the J. F. Hartz Co., of Detroit, Mich., and are in three sizes. They are also made without the perforations. The latter, in my estimation, are of no use, serving only to increase one's labor in cleansing splints. Instead of the side plates being concavo-convex, I have them also made perfectly flat; or what seems to me still better, the septal plate flat and the opposite plate somewhat concave on its outer side for the reception of the opposed turbinal body. The only objection to the latter arrangement is that it somewhat increases the width of the collapsed splint; this, however, is overbalanced by the more perfect apposition of the splint to its anatomical surroundings. These splints, as enumerated, are known as Style "A," with perforations; "B," without perforations; "C," both plates flat; "D," septal plate flat, outer plate concavo-convex. The key of the splint acts also as introducer. The forceps grasps the splints when in position, thus preventing any slipping or twisting. It is my custom to dip them in sterilized olive oil before their introduction. This lubricates the joints in the splint and makes them work without any perceptible resistance.

Arsenic and Iron in the Chloro-Anæmias of Tuberculosis.—Dr. Martinet thinks the following conclusions are tenable: (1) The association of iron and arsenic is rational and justified by clinical experience. (2) The combination is particularly indicated in most chloro-anæmias, and especially in the severe forms approaching pernicious anæmia, with rapid destruction of globules, in torpid and antipyretic tuberculosis, and in the glandular forms. (3) There should be monthly alternation in the administration of protoxalate of iron and of an arsenical water; the administration of tincture of iron and Fowler's solution in equal parts; the administration of arsenate of iron.—*La Presse Méd.*, January 6th.

A SIMPLE AND EFFICIENT RUBBER SPLINT-SHOE.

By H. J. BOGARDUS, M.D.,

JERSEY CITY, N. J.,

SURGEON TO THE NEW YORK ORTHOPÆDIC DISPENSARY.

Probably most orthopædic surgeons have had occasion to recognize the apparent inherent merit of rubber as an eligible material for the shoeing of their hip-splints and other walking-apparatus. Hitherto it has always been difficult to get rubber in a form that would satisfactorily answer the requirements of a splint-shoe. It is known that attempts have been made in the past to secure this desideratum. Some twenty years ago Dr. Taylor used a skilfully moulded rubber splint-shoe, but either because of its expensiveness or its lack of durability owing to its manner of manufacture at that time it never came into general use.

Patients themselves have sometimes appreciated this need, and have come to the dispensary with their worn-out leather splint-shoes replaced with rubber carefully fashioned from some piece of solid rubber taken from the bumpers of cars or from a worn-out clothes-wringer roller, etc.

Not long since, in a casual visit to a carriage maker's establishment, the writer's attention was attracted by some pieces of solid rubber tires, and the present methods by which such tires are secured to the wheels of ordinary vehicles for road use. The idea suggested itself that this form of tire material might be readily adapted for use as splint-shoes, and for the past five or six months a practical test has been made of its efficiency for this purpose at the New York Orthopædic Dispensary, with the most gratifying results.

For the first experiments children were selected who were known to be the most destructive of apparatus, returning at short intervals for repairs and renewal of splint-shoes. By keeping a comparative time record it has been found that the rubber is at least four or five times as durable as the ordinary leather splint-shoe as made by the cobbler.

Besides durability a number of other important advantages may be enumerated in favor of the rubber. It does not involve the expense of special manufacture tor this purpose. It is made for carriage wheels in lengths of about thirteen feet, and all that is necessary to adapt it to the uses of the orthopædist is to cut it in the desired lengths of about three inches. This can readily be done with a sharp wet knife. Worn-out shoes can thus be renewed at the office with the simple help of a screwdriver.

There are no nails, as in the leather splint-shoes, to occasionally trip the patient, or maybe to scratch a polished floor. A brace shod with rubber is less noisy, less liable to slip on the icy pavement, etc.; does not soak up so much of the moisture and dirt of the street; and again, being more elastic, saves the transmission of that much concussion to the patient in walking. The rubber tire can be obtained in a variety of sizes differing in width by one-eighth of an inch.

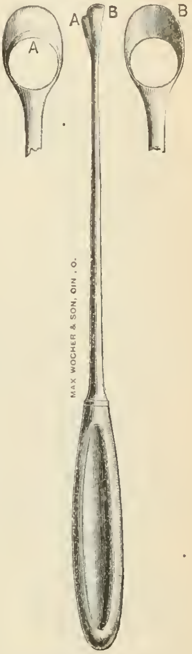
The rubber is fastened to the foot-piece of the splint by means of two ordinary flat-headed machine screws which, passing through countersunk holes in the foot-plate, engage by their threads in a piece of flat steel fitted in the slot that passes longitudinally through the rubber tire. When the screws are tightened the rubber is brought in secure and firm apposition to the under surface of the foot-piece of the brace. At first a piece of sheet brass was fitted over the foot-piece with lips extending down each side acting as flanges to hold the rubber more securely, but practically this has been found to be not really necessary, as the two screws alone hold the rubber firmly in place.

In some instances, if it is necessary to minimize the thickness of the rubber under the foot, a liberal slice may be cut from the convex surface of the rubber and the surface again nicely smoothed off with sandpaper, or, better, by use of an emery wheel.

A NEW CURETTE.

By H. F. GAU, M.D.,

CINCINNATI, OHIO.



This new safety curette is intended for use in those enlarged, softened, infected post-puerperal uteri, in which the use of the average curette is liable to cause perforation of the uterus. The modified curette, which I have named the "safety curette," has an anterior and a posterior cutting surface, with a central perforation varying from three-eighths of an inch anteriorly to one-half an inch posteriorly.

The anterior surface is intended for curetting the anterior, posterior, and lateral surfaces of the enlarged uterus, whereas the posterior edge is better adapted for use on the fundus and the upper angles. Both anterior and posterior edges are protected by a flattened surface, so that perforation of the uterus is impossible. The instrument was presented to the Cincinnati Obstetrical Society at its February meeting.

Therapeutic Hints.

Blennorrhagic Myositis.—Moist heat should be applied, by enveloping the limb in hot boric-acid solution covered with impermeable tissue. After the acute period the following is to be given:

℞ Guaiacol.,	
Ol. amygd. dulc.	p.æ.

S. Apply to limb and cover with cotton.

—Braquehaye and Servel.

Ozæna.—A douche with a Weber siphon should be given, changing the formula for the antiseptic from time to time. After each douching the nose should be sprayed with:

℞ Acid. phenic.	2 gm.
Resorcin	3 "
Glycerini pur.	50 "
Aquæ	300 "

The ulcers should be touched with silver nitrate or zinc chloride solution, and a general tonic treatment given.—*Journ. des Praticiens.*

After douching, a bean-sized mass of the following should be introduced into each nostril, the patient's head being bent back:

℞ Menthol	0.20 cgm.
Boric acid	2. gm.
White vaseline	30. "
Essence of geranium	gtt. xx.

—Bommier.

Trional produces accidents by not being absorbed, when given in water.

℞ Trional.......................... .... 1 gm.
Ol. amygd. dulc...................... 20 "
Sacch.............................. 8 "
Gum. tragac.,
Gum. arab................ ....āā 0.20 cgm.
Aq. aurant. flor...................... 10 gm.
Aq. lauro-cerasi...................... 2 "
M. S. To be taken in half a glass of water.

—POUCHET.

Intestinal Antisepsis in Children.—

℞ Benzo-naphthol... .... 0.05 cgm.
Bismuthi salicylat. (basic)............... 0.10 "
Bismuthi bicarbonat (basic)............. 0.10 "

For one powder. Make five such, and give one every two hours to a child of five or six months of age.

—COMBY.

Coryza.—

℞ Pulv. menthol........................ 0.25 cgm.
Pulv. betol.......................... 2.50 gm.
Cocainæ.............................. 0.50 cgm.
Pulv. caffeæ tost...................... 4. gm.
M. S. Use as snuff.

—*Ann. de Farm.*, Milan.

Eczema of the Ear.—Internal measures should not be neglected in chronic eczema of the meatus. So long as there is acute inflammation arsenic must not be given, but in the scaly stage order:

℞ Sodii arsenat....................... 0.10 cgm.
Aquæ lauro-cerasi........ .... 50. gm.
Aquæ destil.......................... 200. "
M. S. One to four teaspoonfuls daily at meals.

—LERMOYEZ.

Hypodermatically in Syphilis.—

℞ Hydrarg. benzoat........................ 0.30
Sodii chloridi............................ 0.10
Cocainæ.................................. 0.15
Aquæ destill.............................. 40.
Dissolve with heat.

Inject 1 c.c. each day. This must be made fresh at least every fifteen days.—STOUKOWENKOF.

Digestive Infections in Nursing Infants.—After a castor-oil purge:

℞ Benzo-naphthol............... ... 0.[illegible]–0.50 cgm.
Cretæ præpar.,
Bism. subnit....................āā 2 –3 gm.
Mucil. acac .... 30 "
Elix. paregoric .... gtt. vi.–xij.
M. Shake. S. Teaspoonful every hour—less often as improvement follows.

Psoriasis.—

℞ Acid. salicylic .... 3 gm.
Ichthyol.,
Picis.................................āā 10 "
Acid. pyrogallic......................... 6 "
Lanolini seu petrolat.................... 100 "
M. S. Apply.

—BROCQ.

Urticaria.—

℞ Sodii bicarb............................ 20 gm.
Tinct. opii (Sydenham)............. gtt. xx.
Aq. bul.................................. 500 gm.
M. S. Use as a rectal injection.

—DE MAHIS.

Alcoholic Cirrhosis of the Liver.—One of the best diuretics is:

℞ Juniperi fruct .... 10 gm.
Infuse in
Aq. bul.......................... 200 "
Add
Potass. nitrat.,
Potass. acetat......................āā 2 "
Scillæ oxymel.......................... 50 "
Syr. des cinq racines... .... 30 "
M. S. To be taken in four or five doses during the day.

—PLICQUE.

Medical Items.

Christian Science will cure you of what you have not got, or of what is going to get well of itself, just as quickly as any of the 'pathies, and sometimes more pleasantly.

One by Choice.—A Paris journal gives the number of prostitutes registered at 5,183. Of these, 1,440 are forced to the life by poverty, 1,255 are orphans, having no other way to obtain shelter; 280 are widows from the provinces unable to obtain an honest living; 404 are young girls brought from the country by soldiers and others; 289 are domestics discharged after being ruined by their employers; 1,425 have been deserted by faithless lovers; 89 admit adopting this life to support the family. This leaves one to be put down to pure depravity.

Dividends are Improving.—Up to now twenty-five per cent. has been about the limit of the dividend a physician could expect from the sharper to whom he referred his patients. An optical company in Fulton Street has raised the limit to fifty, and will now divide the profits with the physician, share and share alike, as the lawyers put it. These refractionists are paying out, they say, as high as $10 a week to some physicians who send their patients for glasses. A good distributor will soon be able to make a fair income if this sort of thing continues.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended March 24, 1900:

		Cases.	Deaths.

TRAUMATIC HEMORRHAGES INTO THE SPINAL CORD.[1]

BY PEARCE BAILEY, M.D.,

CONSULTING NEUROLOGIST TO THE ST. LUKE'S, ORTHOPÆDIC, AND BABIES HOSPITALS, NEW YORK, AND TO ST. JOHN'S HOSPITAL, YONKERS; ASSISTANT IN NEUROLOGY, COLUMBIA UNIVERSITY.

No one who has to do with injuries to the nervous system now questions the importance, from clinical, pathological, and legal standpoints, of traumatic hemorrhages into the spinal cord. The subject was brilliantly introduced by Thorburn ten years ago; and the contributions of the past few years from Russia, Germany, and this country have entitled it to a distinct place in the surgery of the spinal cord. Yet it continues to receive scant mention in the surgical and neurological text-books, and is inadequately handled even in recent monographs on spinal-cord injuries. As a result, the condition often fails to be correctly diagnosticated, and our knowledge concerning it is not advanced so rapidly as it might be. This is to be regretted from two points of view. First, because traumatic hæmatomyelia is a comparatively frequent lesion; and second, because the chances of recovery, when the symptoms depend upon hemorrhage into the spinal cord, are so much better than in any other variety of spinal-cord injury that the surgeon who fails to recognize the condition exposes himself to great error in prognosis and, maybe, in treatment.

The subject has interested me during the last two or three years; and I have tried to keep abreast of its literature. At the same time a number of cases, both clinical and pathological, have come under my observation. The following paper is based upon the results of these studies. It must not be forgotten, however, that the subject is still in an early stage of its development, and that more observations must be forthcoming before certain personal opinions can be regarded as thoroughly established by fact.

Traumatic hemorrhages into the substance of the spinal cord occur in two ways. First, as complications of general crushes and mutilations, due to fractures and dislocations of the spine. These I have called Secondary Hæmatomyelia. The other and more important variety I have called Primary Hæmatomyelia, as it results from force exerted directly upon the cord itself, without the intervention of pressure by bone or cartilage. Thus, without any fracture or dislocation of the spine the spinal cord may be so twisted or bent within its case, or may sustain a shock, so that its blood-vessels rupture and blood escapes into its substance. A force which ruptures the blood-vessels must at the same time tear nerve fibres and more or less injure nerve cells; and the resulting lesion consequently is a laceration of the cord as well as hæmatomyelia. But unless the laceration is very large it fails to be identified positively by the microscope. For the blood is generally poured out freely and hides minute lacerations; and even if the lacerations were apparent under the microscope, unless they had been so to the naked eye at the time of the autopsy it would be impossible to assert positively that they were not artefacts or the results of destruction which the blood itself had caused. Consequently, while admitting that every case of traumatic hæmatomyelia is associated with some direct injury to the internal parts of the cord, and that such an injury is entirely independent of the destructive effects of bleeding, we are none the less obliged to regard the amount of blood as an index to the severity of the total lesion, and to denominate the pathological condition as hæmatomyelia, though it is more complex than simple hemorrhage. It is the special object of this paper to consider primary traumatic hæmatomyelia. But before passing directly to the main body of the subject, brief mention must be made of the other varieties of injury of the spinal cord with which primary hæmatomyelia might be confused.

In the presence of an injury to the spinal cord, when bullet and other penetrating wounds can be excluded, three possibilities, and three only, present themselves. These are:

I. Pressure from displaced or broken-down protecting structures.

II. Pressure from blood poured out within the spinal canal (Hæmatorrhachis—extra- or intra-dural hemorrhage).

III. Primary hæmatomyelia.

I. Pressure from Displaced or Broken-Down Protecting Structures.—This class comprises the common fractures and dislocations of the spine. The resulting mutilation of the cord is usually extensive, the symptoms are widespread, and the prognosis, though the better for life the lower the region affected, is always gloomy for the restoration of function. The seat of the trouble in the cord can usually, though not always, be inferred from the displacement or abnormal mobility of the vertebræ.

In such injuries hemorrhage occupies a place of varying prominence. It may be extremely slight or absent; or capillary extravasations in the vicinity of the more severe lesion may be found scattered throughout several segments above and below the affected area; in still other cases, the blood makes its way in the gray matter, in pencils or columns, up and down the cord, often for long distances. It is to this latter condition that Van Gieson has applied the name hæmatomyelopore. These hemorrhages take place either immediately and from the same injury as caused the crush, or are the later results of softening and myelitis. They are important for two reasons: One is that a column of blood may extend in the gray matter for some distance above a transverse lesion, causing symptoms peculiar to lesions of the gray matter and different from those attributable to the transverse lesion. The most characteristic gray-matter symptom is the "dissociation" type of anæsthesia, *i.e.*, sensibility to touch preserved, but pain sense and temperature sense lost. Zones of such dissociated anæsthesia are from time to time observed, extending for some little distance above the line of the total anæsthesia symptomatic of the transverse lesion. The other reason for the importance of these secondary hemorrhages is found in the cases in which with a fractured vertebra, the external pressure effects upon the cord are slight; but in which the same force which caused the fracture caused a hemorrhage into the cord substance; so that the symptoms are the combined results of pressure exerted by bone externally and by blood internally. Such cases merge toward the category of primary hæmatomyelia.

---

[1] From the Department of Pathology, College of Physicians and Surgeons, New York.

The vast majority of injuries to the cord resulting from fractures and dislocations present no difficulties of diagnosis. The history of the accident, the bone deformity, the sudden and persistent paralysis of motion, sensation, and sphincter action leave little opportunity for error. But when one or more of the cardinal symptoms are absent—when the spine appears intact or there is no anæsthesia, when the paralysis of motion is limited or incomplete, or the sphincters are not affected, the problem becomes more difficult. Partial lesions of this class may resemble, in symptoms and causation, primary traumatic hæmatomyelia; and, indeed, it is probable that secondary hemorrhage is responsible for part of the symptoms in such cases. The diagnosis of partial lesions arising from external pressure is assisted by remembering that the symptoms are chiefly due to pressure exerted upon the outside of the cord, *i.e.*, upon long afferent and efferent tracts, rather than upon the central gray matter. Consequently, however slight the symptoms may be, they are found everywhere below the lesion. Thus, in the case of an injury in the cervical region, paralysis or impairment of sensation and motion will involve both arms and legs; in other words, evidences of the injury will be present everywhere below it.

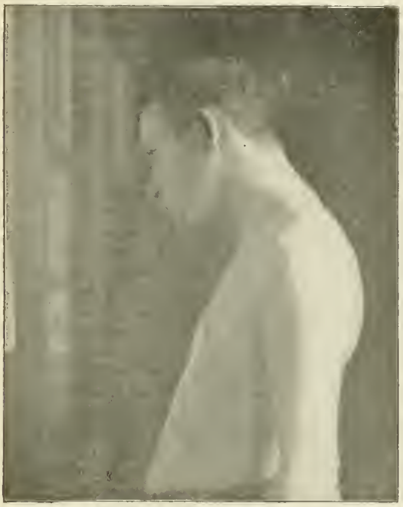

FIG. 1.—Attitude in the Case of a Partial Lesion of the Spinal Cord, due to injury of the cervical vertebræ.

Since hemorrhage has a predilection for the central parts of the cord, a small focal hemorrhage within the cord substance produces a very different clinical result. As will be explained further on, primary hæmatomyelia may cause symptoms in the upper extremities, while the lower extremities are unaffected—*i.e.*, no injury to long conduction tracts.

The dissociated type of anæsthesia also is, as far as our present knowledge goes, distinctly characteristic of a gray-matter or central affection.

Finally, lesions due to compression from without the cord are, as a rule, richer in symptoms than purely hemorrhagic ones. There is usually impairment of both sensation and motion in extended areas; also the bladder rarely escapes involvement. However, it is not to be denied that in some cases the symptoms following fracture or compression from the outside are extremely slight. The following case shows this:

The patient, W. A. B——, thirty-six years of age, a previously healthy man, and always well except for troubles directly induced by drink, fell on December 9, 1898, about fifteen feet into an area way, landing on the head. He was picked up unconscious, and found himself in Bellevue Hospital the next morning. The scalp was badly contused and lacerated; there were great pain and tenderness and some swelling of the neck. There was no paralysis, but both arms and both legs were weak, the weakness being especially noticed on the left side. There were tingling of the fingers and numbness of the arms and legs. There were no disturbances of the bladder or rectum. After eleven days the patient was well enough to walk out of the hospital. Since then the chief sources of annoyance have been pain and stiffness in the neck and numbness in the extremities of the right side.

Examination, January 25, 1899, Vanderbilt Clinic: The patient (Fig. 1) holds the head bent forward on the chest and is either unwilling or unable to make free movements with the neck. Efforts at movement done either by him or by the examiner cause severe pain. The seventh cervical spine is so unduly prominent that, although there is no crepitus, false motion, or other evidences of fracture, it seems certain that there has been either fracture or dislocation in this vicinity. The symptoms pointing to a nervous lesion are a partial hemianæsthesia on the right side, and a contracted pupil, with some sinking in of the eyeball and narrowed palpebral fissure on the left (cilio-spinal centre). The hemianæsthesia is very indistinct in its upper boundaries. It does not involve the face and begins at about the clavicle. In the upper extremity it is more definite and in the leg it is pronounced. It includes all qualities of cutaneous sensibility. There is also anæsthesia of the index finger of the left hand. All the muscles of the extremities seem somewhat weak, but there is no demonstrable paralysis. There is no localized atrophy, no fibrillation, no foot clonus. The knee jerks are lively, especially the left one, but not excessively exaggerated. The absence of paralysis, of sphincter troubles, and of marked changes in the tendon reflexes, shows that the injury to the cord was extremely slight. It is unusual for such slight injuries to be caused by a fracture or dislocation. But that a bone lesion, causing pressure upon the outside of the cord, was at the bottom of the symptoms in this case, seems probable. There were deformity and extreme pain in the back; the motor disturbances, slight though they were, involved all four extremities, and the hemianæsthesia bespoke a lesion affecting the long afferent sensory paths.

II. Pressure from Blood Poured out Within the Spinal Cord.—The second class, hemorrhage between the cord and the vertebræ (either extra- or intra-dural) has received much more attention by clinicians than it is entitled to by autopsy records. Surgeons are constantly on the alert for it, in the belief that it is amenable to cure by the knife. It is sometimes given a distinct symptomatology in text-books. Yet my own experience and a careful study of the literature have persuaded me that this lesion is rarely if ever of clinical importance. If it occurs as a distinct and isolated pathological entity, there are no reliable means of recognizing it during life. It is true that it is met with from time to time in autopsies on traumatic cases, but never, so far as I have been able to determine, as an isolated lesion. It is invariably associated with the far more important injuries of crushes or intraspinal hemorrhage, which latter conditions give the clinical stamp to the case. It is needless to say that they would remain unaffected, in symptoms and course, even were the external blood clot removed. This extramedullary hemorrhage is sometimes invoked (notably by Kocher) in explanation of the characteristic symptom complex known as "diplegia spinalis brachialis traumatica." That this condition can be better explained by hemorrhage within the cord than without it will shortly be shown.

III. Primary Hæmatomyelia.—The third variety of spinal-cord injury, primary traumatic hæmatomyelia, it is the special object of this paper to consider. The condition, as already intimated, is relatively frequent, but its special clinical importance results from its favorable prognosis. The subject is yet too young to permit any accurate estimate as to the ratio in which this particular variety of lesion stands with respect to the total number of spinal-cord injuries. Some facts are, however, accessible. Of twenty-one cases of spinal-cord traumatisms examined by Thorburn, six were interpreted as examples of primary hæmatomyelia. Of seven cases of general injury examined by Parkin, one was primarily hæmatomyelia. Of Stolper's twenty-two autopsies on various spinal-cord injuries, two were primary hæmatomyelia. Thus, autopsy records show that injury causes hemorrhage into the substance of the spinal cord, without demonstrable lesions of the bones, in a considerable number of cases. This percentage would undoubtedly be much higher if more statistics could be obtained of partial lesions; for there is good reasons to suppose from clinical data that a large proportion of cases of partial lesions are of hemorrhagic origin. But as the patients in such cases are much more apt to recover than to die, they are useless as far as the statistics of pathological anatomy are concerned.

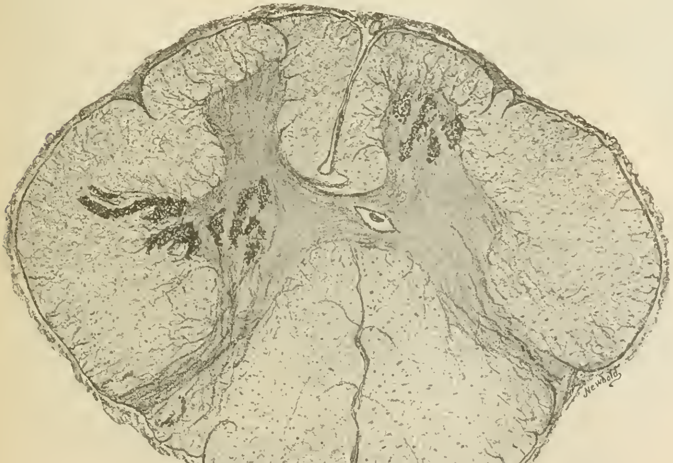

Fig. 2.—Small Hemorrhages into the First Thoracic Segment of the Spinal Cord, following a severe general traumatism. Spinal column uninjured.

The situation of the hemorrhage is usually in the gray matter. This is explained by the gray matter being more highly vascularized and by its having less supporting tissue than have other parts of the cord. When the hemorrhage is extensive, it may burst beyond the gray matter into surrounding areas. The ventral and the dorsal horns are the favorite sites. The gray commissure often escapes, and it is unusual for it to be involved in the immediate vicinity of the central canal.

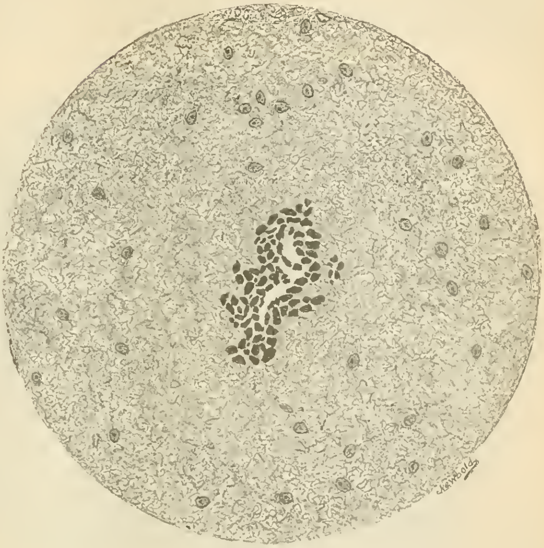

Fig. 3. Small Hemorrhage into the Spinal Cord. No inflammatory or degenerative reaction.

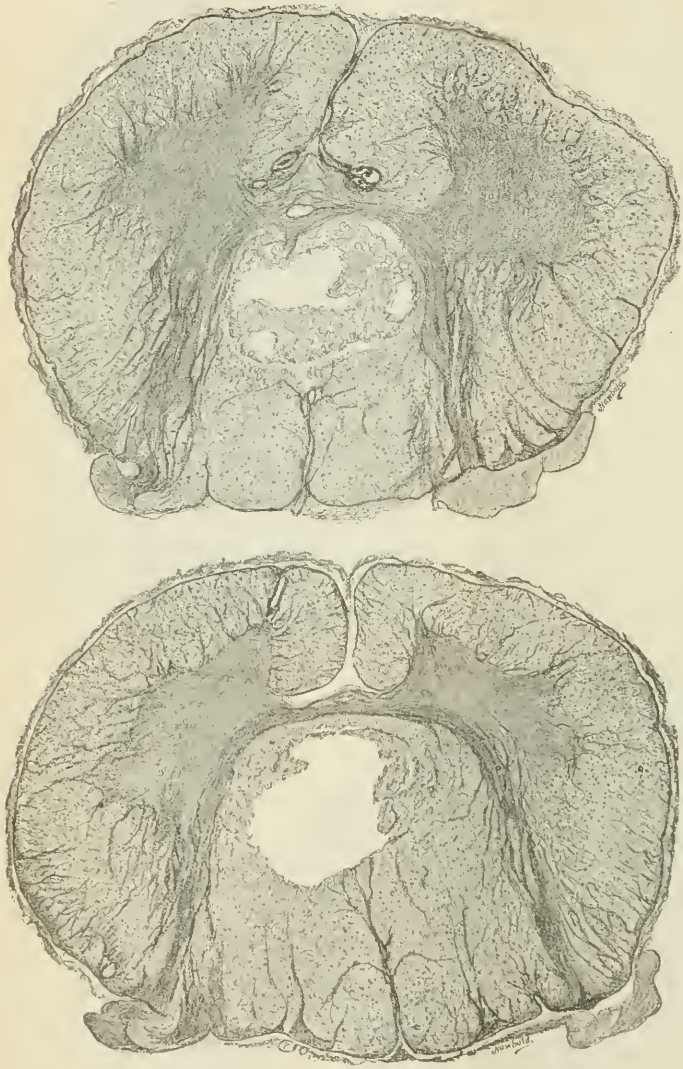
The white matter is not left entirely free, if the hemorrhage is at all extensive. It may be involved by the blood passing the limits of the neighboring gray, or the whole white matter may be spotted with small extravasations. Large hemorrhages into the white matter are most frequently found in the dorsal columns just behind the gray commissures. The size of the individual hemorrhages varies within wide limits. A single hemorrhage may extend, in an unbroken column, through several segments. In some of the reported cases the cord at the affected level has been completely hollowed out by the blood clot. In others, the blood, though extending widely, has left some of the cord free. In others, as in Fig. 2, the hemorrhage is extremely small and more marked on one side than on the other. The patient from whose spinal cord this drawing was made died ten days after a severe general traumatism involving rupture of the liver and kidneys. Between the receipt of the injury and the time of death he was conscious, could walk, and complained of no symptoms to call attention to the nervous system. But had he been carefully examined it seems probable that the existence of the hemorrhage, small as it was, might have been recognized. For it occurred in that most important segment, the first thoracic, which is concerned with the cilio-spinal reflex and with the fine movements of the fingers, and in which even very small lesions cause symptoms recognizable by the trained examiner.



Figs. 4 and Showing Cavity Formation in the Spinal Cord as the Result of Hemorrhage.

These focal hemorrhages are usually surrounded by some smaller extravasations which may be invisible to the naked eye or may appear as minute dots. It is usually impossible to tell without the aid of the microscope whether the blood in such cases is extra- or intravascular. When the hemorrhages are small, they do not cause any visible inflammatory or degenerative reaction in the cord (Fig. 3). Large hemorrhages may be surrounded by areas of softening. In many cases of large hemorrhages, however, the action of the hemorrhage seems almost entirely mechanical. The blood pushes its way through the cord substance, and destroys as it goes. As it disintegrates and is absorbed together with the destroyed nervous tissue, there results a cavity in the cord. Fig. 4 shows the mechanism of the formation, in an early stage, of such a cavity. The spinal cord is that of a man who sustained a fracture of the fifth cervical vertebræ, and died in five days. There was extensive mutilation in the sixth cervical segment with ascending and descending columns of blood. The ascending column went through the posterior column just behind the gray commissure. Figs. 4 and 5 show the condition of the fourth and third cervical segments, the latter segment being the upper limit of the hemorrhage. The blood and destroyed nervous tissue have not had time to be entirely absorbed. In Fig. 5 the disintegrated area dropped out during the manipulation of the cord for microscopic purposes, leaving a cord apparently healthy except for the loss of substance. This loss appears as a clearly punched-out hole, around the edges of which are clinging broken-down blood cells. When the patient lives for some time after the injury, it is the tendency for such cavities to be filled up more or less completely with neuroglia tissue. Fig. 6 shows a section of the cord at the eighth cervical segment of a man who died seven months after an extensive primary traumatic hæmatomyelia. At autopsy the cord was flattened from before backward, and the outlines of the gray matter were lost. The central part of the cord was occupied by new tissue, with cracks and slits throughout. Microscopic examination showed that this was new connective tissue, containing many and variously shaped spaces, some of which were filled with broken-down blood. What had undoubtedly taken place in this cord was hemorrhage into the gray matter; partial absorption of blood and broken-down nerve elements, and outgrowth of connective-tissue cells from the limits of the original cavity, gradually decreasing the size of the latter. Such hæmatogenous cavities have no epithelial lining and are not ordinarily connected with the central canal. They may resemble very closely the conditions found in syringomelia, and the symptoms to which they give rise are often surprisingly like those of syringomyelia. Some writers have gone so far as to refer to such cases as traumatic syringomyelia. It seems to me, however, that they should be kept distinct in name from the chronic progressive and probably congenital spinal disease, as they are distinct in origin, and that they should be designated as primary hæmatomyelia.

Localized collections of hemorrhage from injury are found very much more frequently in the regions of the cord subjacent to the lower cervical vertebræ, *i.e.*, in the region of the greatest spinal movements. The corresponding spinal cord segments are the fifth, sixth, seventh, eighth cervical, and first and second thoracic. It is probable also that primary traumatic hæmatomyelia occurs in the lower lumbar region and in the conus medullaris. In the majority of the cases of hemorrhage in this region, however, there have been serious lesions in the bones.

Such hemorrhages as have now been described are usually localized or focal. The largest hemorrhage may be surrounded by smaller collections of free blood cells, but the hemorrhagic region is limited to one region of the cord, and beyond it the cord is normal.

In contrast to this type of hæmatomyelia is another, the disseminated type, in which there are extravasations throughout the whole spinal axis. This is a variety of hæmatomyelia which has been much speculated upon as affording an anatomical foundation for the traumatic neuroses. It has been found at autopsies on infants born after prolonged and difficult labor. But with the exception of a case described by me,[1] I have found no pathological records of it in traumatic cases in adults.

An epitome of the case referred to is as follows:

A workman received a severe fall and died in three hours. The autopsy showed a hemorrhage into the middle fossa of the skull without fracture. There was a fracture dislocation of the atlas and axis, with extensive mutilation of the cord at this point. Except at the point of compression, the cord looked in every way normal. On section it could be seen that the blood vessels were somewhat prominent, but the eye could detect no free blood either at the seat of injury or at lower levels. Sections were made of every segment of the thoracic, lumbar, and sacral regions and examined microscopically. The lesions found were generally distributed up and down the cord, and consisted of recent capillary hemorrhages. No single hemorrhage contained over two or three hundred blood cells, and the majority of them contained fewer. In some places there were only two or three free cells. In a few sections the blood lay in little cavities, but the most common distribution of it was in the form of an infiltration of a small number of blood cells between the neuroglia and nerve fibres. There was nowhere any tubular cavity formation. The largest extravasations were in the pia and around the nerve roots. In the spinal cord, although occurring in the gray matter, they were most frequent in the white matter, especially in the posterior columns. Nearly every section contained the hemorrhages, but no section contained very many, usually not more than two or three. The situation of the hemorrhages bore little or no relation to the location of the large blood-vessels. The blood-vessels were prominent and filled with blood. In all other respects the spinal cord appeared normal.

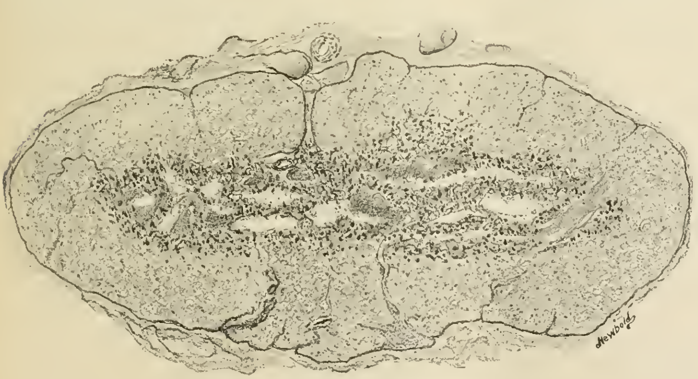


Fig. 6.—Showing Late Results of Cavity Formation. The central parts of the cord, into which hemorrhage had taken place, are being filled up with new connective tissue.

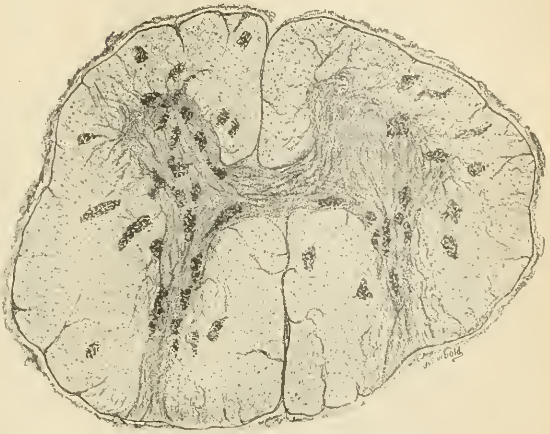

Fig. 7.—Disseminated Hemorrhage into the Spinal Cord from Injury.

Thus, to resume briefly, a healthy man fell with sufficient violence to break his neck and to cause an intracranial hemorrhage without fracture of the skull. The force was exerted chiefly on the atlas and axis, as seen by the injury to these bones. But it was also adequate to cause throughout the cord punctate hemorrhages, which were entirely unassociated with the severe local injury and which were probably due to the general violence to which the whole spinal cord was subjected.

Since the publication of the foregoing, two other similar cases have come to my observation. Of these, one came to me through the courtesy of Dr. P. R. Bolton from the Hudson Street Hospital, the other from Dr. Eugene Hodenpyl's pathological service at the Roosevelt Hospital.

Case I.—An adult workman fell through a hatchway and died in two days. An autopsy was made four hours after death. There was a fracture of both laminæ of the sixth cervical vertebra. Otherwise the spinal column was normal. The cord was softened and discolored in the lower part of the cervical region—*i.e.*, the region subjacent to the fracture. There was also a similar area of softening in the lower thoracic region.

---

[1] "Accident and Injury; their Relations to Diseases of the Nervous System," New York, 1898.

Microscopical examination: The chief lesions in this case were small hemorrhages throughout the whole cord from the upper cervical to the lower lumbar region. They were especially pronounced in the region subjacent to the fracture and in the part of the cord included between the seventh and tenth thoracic segments (Fig. 7). The most serious damage was in the eighth cervical and first thoracic segments. Here the hemorrhages in both gray and white matter were very numerous and comparatively large, and were associated with a slight condition of softening, characterized by Glüge's corpuscles, myelin drops, and disintegration of nervous elements. There were similar appearances in the lower-lying focus of severe lesion. In addition to these two foci of most pronounced injury, capillary hemorrhages were present throughout the spinal axis from the second cervical to the lower lumbar segments. Above the second cervical and below the lumbar enlargement they were least frequent and prominent. The collections of blood throughout the affected segments varied in size and number. In some places only a few blood cells had been extravasated, in others they were more numerous. The largest hemorrhage was not over 3 mm. diameter, and none could with certainty be identified with the naked eye. In the most seriously affected regions the sections were studded throughout with the blood collections; in the other segments they were chiefly, though not exclusively, confined to the gray matter. In many of the larger hemorrhages there was degeneration in the centre so that the outlines of the blood cells were lost. In some of these there were fissures which, had the patient lived, would have gone on to cavity formation. The finer structure of the ganglion cells could not be determined, as the cord had been put in Müller's fluid; they seemed, however, except when directly involved by the blood, to be normal in number and size. The nerve fibres were, in general, well preserved. The blood-vessels were prominent and filled with blood throughout. Their coats were not thickened.

Case II.—A boy, two and a half years of age, fell down a flight of stairs, at the foot of which he was found unconscious. Four hours later, without regaining consciousness, he died. I did the autopsy four hours after death. The temporal and parietal bones of the skull were fractured, and there was an extensive subdural hemorrhage in the middle fossa, extending up over the convexity of the brain. The spinal cord was removed with especial care to avoid bruising. Macroscopically it appeared normal. Studied through all its segments in microscopic section it appeared normal in respect to topography and essential elements. The blood-vessels were not thickened nor unduly prominent. In the cervical and lower thoracic regions there were small capillary hemorrhages situated chiefly in the dorsal horns of the gray matter and on the dorsal white columns. They contained only a few blood cells, were in no apparent relation to the blood-vessels, and produced no secondary consequences in the structure of the cord.

In reporting cases of this character I am well aware of the danger of error of interpretation of such lesions, and of advancing as pathological what are in reality artefacts due to post-mortem mutilations. But that the free blood cells in the cases recorded here were in reality extravasated, and that they occurred before death as the direct results of the physical injury, I am confident for the following reasons:

1. All the patients suffered fatal traumatisms. 2. The cords were removed with especial care. 3. All gross evidences of internal or external bruisings were absent. 4. Such punctate hemorrhages are not found in spinal cords, removed in the ordinary way, unless there is a history of injury. 5. The wide dissemination of the hemorrhages. If they were artefacts, they would probably be focal. 6. The fact that in many places the blood had degenerated is conclusive proof that it had been poured out before death.

These cases must be accepted, therefore, as proving that severe general injuries can cause disseminated lesions throughout the spinal axis. Although the vertebral column was intact in only one of the cases, the bone injuries were confined to one point, and the hemorrhages existed so far from that point that they unquestionably arose independently of any local effects of compression, and would in all probability have occurred even if there had been no fracture of the spine.

The clinical importance of these disseminated hemorrhages will be referred to a little further on.

Clinical Considerations.—For clinical purposes primary hæmatomyelia can best be considered under three heads: A. Large focal hemorrhages. B. Small focal hemorrhages. C. Disseminated hemorrhages.

A. Large focal hemorrhages: In an article read before the Johns Hopkins Hospital Medical Society[1] I described this condition at some length. A brief *résumé* of certain parts of that article may make the present one more complete.

After certain injuries by which the neck is forcibly flexed or, perhaps, extended, there develops immediately a condition of motor paralysis, variously distributed, together with peculiar sensory symptoms. The paralysis of voluntary motion, with few exceptions, ensues instantly upon receipt of the injury. The muscles involved at the level of the injury (since the hemorrhage is most constant in the lower cervical region) are those of the forearm and hand, and sometimes of the upper arm; those below, of the lower extremities. The paralysis of the upper extremities has a different anatomical basis from that of the lower. The first is due to the blood being poured directly into the spinal nuclei of the brachial nerves, thus constituting a destructive lesion. From such a condition perfect recovery is improbable, and, in fact, most of the patients remain permanently paralyzed, though the paralysis may be very limited in some of the muscles of the upper extremity. The paralysis of the legs, on the other hand, is the result of conditions often permitting recovery. The most plausible explanation of this paralysis, from which recovery may be expected, is that the hemorrhage, although occupying the central portions of the cord, exerts sufficient pressure, or is followed by œdema sufficient to compress for a time the pyramidal tracts which lie a little distance from it, and which are carrying the long cerebral fibres destined for the muscle nuclei situated at lower levels. When the hemorrhage ceases, the commotion it has caused in its vicinity subsides and the pyramidal fibres are permitted to resume their wonted function. The distribution of the paralysis varies with the situation and extent of the hemorrhage. If below the first thoracic segment, an unusual situation, the arms escape. If above the second thoracic segment, the paralysis affects the muscles whose nuclei are below the upper limit of the hemorrhage. If the hemorrhage is on one side of the cord only, affects the arm chiefly or only; if larger, but still confined to one side, there is spinal hemiplegia.

In a large number of cases the hemorrhage is sufficient to cause at first paralysis of both arms and of both legs. When the patient is seen immediately after the accident, the paralysis is flaccid in character, the muscles are soft and yielding, without rigidity, and the paraplegia is complete. The knee jerks are diminished or lost (this does not of itself indicate a transverse lesion, as is often maintained). When the lesion is very small, the knee jerks may be hypertypical or exaggerated at once. In the lower extremities the paralysis soon undergoes a change, and from being flaccid it becomes spastic. The knee jerks, if they are diminished or lost, return and become exaggerated, and ankle clonus is added.

---

[1] "Primary Focal Hæmatomyelia from Traumatism," New York Medical Record, November 19, 1898.

With the establishment of spasticity strength returns to the legs. Some patients are able to walk a few weeks after being completely paraplegic. The recovery in the legs comes sooner than that in the arms; in the arms it is also less perfect than in the legs, there usually being left a permanent atrophic paralysis in some of the brachial muscles.

Of these muscles the most frequently affected are the small ones of the thumb and the interossei. Thus, a patient recovering from this affection may present a picture very similar to that of progressive muscular atrophy (amyotrophic lateral sclerosis), viz., a paralysis of the upper extremities of the peripheral neuron type, with atrophy, fibrillation, and degenerative electrical reactions, and of the lower extremities of central neuron type, with rigidity, increased knee jerks, and ankle clonus.

When distinctive sensory symptoms are added to those of progressive muscular atrophy, the picture changes to that of syringomyelia, and, as has often been emphasized, primary focal hæmatomyelia from trauma has many things in common with syringomyelia. The sensory symptoms in these cases differ materially from the sensory symptoms observed in transverse lesions.
